Lowering the storage temperature below an optimum threshold will reduce damage caused by insect pests. Stored-product insects are generally unable to reproduce below 18℃ and cannot move below 5℃, whereas temperatures between 15℃ and -15℃ will eventually kill them. The lower the temperature, the faster the insects will succumb to cold injury. Stored-product insects are unable to survive freezing between -10℃ and -18℃. Species, sex, developmental stage, temperature level, relative humidity, product moisture, acclimation, product type and other factors that determine pest susceptibility to cold are examined. Low temperature strategies as well as existing and potential technologies that might be considered for cold treatments in storage facilities such as ambient aeration, chilled aeration, grain turning, freezing etc. are described. The mode of action, cost, effectiveness, practicality, limitations, hazards, integration with other IPM methods and possible areas for future research for cold treatments in storages are investigated. The main goal of this review is to demonstrate how cold treatments can practically prevent or control insect infestations in stored products focusing on grain and seeds, dried fruits and nuts, flours, and processed and packaged foods.

Keywords:*stored product insects, integrated pest management, cold treatment, extreme temperature*

Occurrence and level of phosphine resistance in stored-product insects in Oklahoma USA

George Patrick Opit[1], Thomas W. Phillips[2], Michael J. Aikins[3], Mahbub M. Hasan[4]

[1]Oklahoma State University, U.S.A., [2]Kansas State University, U.S.A., [3]Kansas State University, U.S.A., [4]Rajshahi University, Bangladesh

Phosphine gas, or hydrogen phosphide (PH3), is the most common insecticide applied to durable stored products worldwide and is routinely used in U.S. for treatment of bulk-stored cereal grains and other durable stored products. Research from the late 1980s revealed low frequencies of resistance to various residual grain protectant insecticides and to phosphine in grain insect species collected in Oklahoma. The present work, which employed the same previously established discriminating dose bioassays for phosphine toxicity as in the earlier study, evaluated adults of nine different populations of red flour beetle, Tribolium castaneum, and five populations of lesser grain borer, Rhyzopertha dominica, collected from broad geographic locations in Oklahoma. One additional population for each species was a laboratory susceptible strain. Discriminating dose assays determined eight out of the nine T. castaneum populations, and all five populations of R. dominica, contained phosphine-resistant individuals, and maximum resistance frequencies for these species were 94% and 98%, respectively. Dose-response bioassays and logit analyses determined that LC99 values were approximately 3 ppm for susceptible and 377 ppm for resistant T. castaneum, and approximately 2 ppm for susceptible and 3,430 ppm for resistant R. dominica. The most resistant T. castaneum population was 119-fold more resistant than the susceptible strain and the most resistant R. dominica population was over 1,500-fold more resistant. Results suggest a substantial increase in phosphine resistance in these major stored-wheat pests in the past 20 yr, and these levels of resistance to phosphine approach those reported for other stored-grain pest species in other countries.

Practical implications of insecticide resistance in stored-product insects

Raul Narciso Carvalho Guedes
Federal University of Vicosa, Brazil

Stored-product protection in warmer climates is largely dependent on insecticide use. The ever increasing safety and environmental concerns added by requirements of high control efficacy imposes restrictions to these compounds and how they can be explored. Furthermore, insecticide resistance is a frequent problem among these insect pest species. This phenomenon is a serious concern in itself since it increases control costs, impairs control efficacy and may lead to insecticide overuse consequently increasing their risk to human and environmental safety. In addition, the expression of insecticide resistance is potentially associated with sub-lethal effects, particularly behavioral effects, which can affect the relationship of the target species and other components of their environment, including natural enemies and other insect pest species. Such components may in turn exhibit indirect effects on the target species under an insecticide-impregnated environment. The sub-lethal effects may even favor higher rates of pest population growth in the target species and the insect behavior when exposed to such compounds may lead to avoidance of toxic exposure. As sub-lethal exposure is likely under practical conditions of insecticide use in stored products and the co-occurrence of different pest species and their natural enemies is expected in such conditions, they should be considering when assessing the impact of insecticide resistance in stored product insects since they are likely to compromise even further insecticide efficacy and their associated problems.

Recent advances in fumigation for control of insect pests in stored grain

YongLin Ren
Murdoch University, Australia

Phosphine has been scheduled for a toxicological and residue Re-Evaluation Review in 2014 by the FAO Codex Alimentarius organisation that sets internationally agreed maximum residue limits (MRLs) for pesticides. Murdoch University Postharvest Plant Biosecurity Research Laboratory has investigated the fate of 32P labelled phosphine in grain and grain fractions. Radioactively-labelled phosphine is a useful and sensitive tool to study residue of phosphine in grains and their fractions. This research will assist industry to conduct good phosphine fumigation practice. Fumigation of grain, fruit and empty cells with ethyl formate has been evaluated and different formulations, eg., liquid ethyl formate, ethyl formate (95%) + MITC (%%) and ethyl formate (16.3%) + CO2 (83.7%) and different application methods has been developed. Ethanedinitrile (EDN) is a methyl bromide (MB) alternative fumigant has been shown to have potential as a quarantine treatment for timber. Unlike MB, SF and PH3, the penetration of EDN into timber blocks occurred with and across the grain of the timber block. Ethanedinitrile is also a great fumigant for soil to control insects, nematodes, pathogens and weeds. It could be potential to replace MB as a fast fumigant for pre-shipment treatment and for devitalisation of imported grain in Australia. ProFume is Sulfuryl fluoride (originally developed by the Dow Chemical Company) registered for fumigation of grains. As a fumigant, it shows low sorption on grain, non-flammable gas, and with highly toxic to the most stored grain insects at adult stage, but egg stage is more tolerance.

Recent advances in fumigation for control of insect pests in dried fruits and nuts

Spencer Walse
USDA ARS, U.S.A.

United States agricultural industries are facing, with increasing frequency, environmental and pest-related food safety requirements that are fundamentally difficult to balance. Failure to properly sanitize foodstuffs in trade and marketing channels can result in insect- and microbial-derived damage that limits economic profitability, curtails market access, and vectors plant, animal, and human illnesses. Despite a historic precedence of effectiveness, the use of chemicals, including fumigants, for disinfestation and disinfection of foodstuffs is under close regulatory supervision due to consumer consciousness regarding unintended health effects resulting from chemical residues. Regardless of personal viewpoints, or merit of scientific backing, chemical treatment advocacy and opposition is expected to continue. This presentation describes experimental infrastructure and critical research elements of the Crop Protection and Quality Research Unit of the USDA-ARS-SJVASC that specifically address this contemporary dilemma, one that will only become more challenging and important as the role of the United States in feeding the world expands over the next decades. In particular, recent developments in postharvest chamber fumigations are presented, such as methyl bromide and alternative phytosanitary treatments for insect control, strategies to limit or reduce emission of fumigants to the atmosphere, and novel technologies for residue removal.

Current status of non-chemical methods for control of insect pests in dried fruits and nuts

Judy Ann Johnson
USDA ARS, U.S.A.

Regulatory agencies and consumers have no tolerance for live insects in dried fruit and tree nut commodities; consequently, successful marketing of these products requires postharvest treatments designed to kill any pest insects. Recent regulatory actions have severely limited the use of chemical fumigants by US dried fruit and nut processors to control postharvest insect populations. Non-chemical treatments would provide an alternative to fumigation, and would also be useful to organic processors. One proposed treatment uses radio frequency energy to rapidly heat walnuts to an average temperature of 60°C for 5 minutes. Large-scale tests using an industrial radio frequency heater successfully disinfested walnuts of navel orangeworm while maintaining good product quality. A second alternative exposes product to a low pressure environment of 50 mm Hg in flexible polyvinyl chloride containers. Temperature and moisture content of the product strongly affects treatment efficacy, with complete mortality of test insects achieved at treatment exposures of 48-72 hours under optimal conditions. Another alternative is the use of cold storage (0-5°C) to either disinfest product or prevent reinfestation of clean product, and may be effectively combined with other non-chemical treatments. At temperatures of 0 and 5°C, 95% mortality of test insects was achieved at 10 and 18 days, respectively. Storage at 10°C prevented reproduction, product damage and reinfestation, but 127 day exposures were required to kill 95% of Indianmeal moth larvae. While these non-chemical treatments are effective, they usually require considerable capital investment and modification of existing processing plants, slowing their adoption by the industry.

The importance of being postharvest

Lisa Neven[1], Wee Yee[2]
[1]USDA ARS, U.S.A., [2]USDA ARS, U.S.A.

Postharvest Entomology is often an afterthought when considering insect pest management strategies of fresh agricultural commodities destined for export markets. Unfortunately, the success of pest management programs for these commodities may be negated due to import restrictions based on quarantine concerns. In these situations, the postharvest entomologist must be flexible and innovative in identifying the pest problem, examining the production, harvest, and processing procedures, and developing the most effective approach to achieve quarantine security while maintaining economic viability of the production system. Many times, attainment of quarantine goals will include a direct postharvest treatment, such as methyl bromide fumigation or irradiation. However, the axiom "no treatment is the best treatment" is a consideration that should be on the forefront of any postharvest entomologist's mind. These 'non-treatment' alternatives to attaining quarantine security can include determination of host status, establishment of areas of low pest prevalence and pest free zones, identification of pathways to facilitate systems approaches, and development of ecological niche models to generate biorational pest risk analyses. All of these approaches, from direct commodity treatments to ecological niche modeling, have been utilized in addressing insect pest quarantine requirements for tree fruits from the Pacific Northwest of the United States of America and will be discussed in this paper.

Heat as a postharvest disinfestation treatment for floricultural crops

Arnold Hajime Hara
University of Hawaii at Manoa Department of Plant and Environmental Protection Sciences, U.S.A.

Heat in the form of hot water was first used as a disinfestation treatment to treat seed potatoes for late blight in 1882. . Heat treatment has been used to control fungal, bacterial and viral diseases, plant-parasitic nematodes and insect pests, but was shelved for about 50 years with the advent of nerve poisons (DDT, diazinon) and chemical fumigants (methyl bromide). Heat treatments not only control pests and diseases, but are a benefit to certain plants by increasing rooting, budding and vase life. Plants sensitive to heat injury can also be conditioned to tolerate heat treatments. Hot water treatment for 45-49 C (113-120 F) for 10 to 15 min disinfests flowers, foliage, potted plants, propagative cuttings, and media of many pests of quarantine significance, including ants, aphids, mealybugs, scale insects, plant-parasitic nematodes, snails and slugs. Hot water dips of tropical propagative cuttings can be used to disinfest cuttings of insects, nematodes and pathogens with the side benefit of increase in rooting. Hot air at 40 C (104 F) conditions plants, foliage and flowers to tolerate hot water and at 44 C (112 F) controls thrips and other insects. Use of steam to pasteurize (149 F for >30 min) or sterilize (185 F for >30 min) plant media will disinfest the media of fungal and bacterial pathogens and plant-parasitic nematodes. Heat is an effective and sustainable postharvest pest and disease disinfestation treatment for export floricultural crops.

Oxygenated phosphine fumigation for postharvest pest control

Yong-Biao Liu
USDA ARS, U.S.A.

Oxygenated phosphine fumigations (fumigations under superatmospheric oxygen levels) were found to be significantly more effective than the regular fumigations under the normal 20.9% O2 against different life stages of all six insect species tested including western flower thrips (Frankliniella occidentalis), leafminer (Liriomyza langei), grape mealybug (Pseudococcus maritimus), Indian meal moth (Plodia interpunctella), light brown apple moth (Epiphyas postvittana), and lettuce aphid (Nasonovia ribisnigri) at low temperatures. Oxygen level of 30-80% were tested. Oxygenated fumigations under 60% oxygen resulted in significant reduction in treatment time and phosphine concentration to control the insects as compared with the regular phosphine fumigation. Oxygenated fumigation was also effective against eggs of grape mealybug and light brown apple moth which were tolerant to regular phosphine fumigations. Oxygenated phosphine fumigation was also compared with the regular fumigation with cylinderized pure phosphine to control lettuce aphid on lettuce. The oxygenated phosphine fumigation was significantly less phytotoxic to lettuce than the regular phosphine fumigation due to reduced treatment time and low phosphine concentration. Past research also shows that oxygen has ignition suppression effects on phosphine. Therefore, oxygenated phosphine fumigation can be conducted safely. Oxygenated phosphine fumigation seems to have several advantages over the regular phosphine fumigation and have a great potential to develop more effective and safer treatments for postharvest pest control on both fresh and durable commodities.

Pest ants of urban importance

Michael K. Rust
University of California, U.S.A.

In recent years, the importance of ants as pests in urban environments has gained considerable attention. Their importance in the US is only second to termites. Of the some 11,800 species described, a relatively small number have readily adapted to urban environments and become significant pests. In the US, about 50 species are regularly encountered around structures, most not serious pests. Many of the serious pests are considered to be so-called "tramp ants" such as Argentine ant, red imported fire ant, Pharaoh ant, and little fire ant. These exotic species thrive in urban disturbed habitats and have the ability to displace native species. Other native species such as carpenter ants, odorous house ants, and field ants may invade certain urban settings especially in situations where structures are close proximity to native habitats. Stings and bites of certain species have always been of medical concern, but in recent years, more attention has been given to ants that serve as mechanical potential vectors of human disease or may pose an asthma problem. The widespread use of sprays and granular insecticides around the perimeters of structures to control ants has raised concern about its impact on insecticide runoff into urban waterways.

Argentine ants - understanding their behavior for effective management

Dong-Hwan Choe
University of California, U.S.A.

The Argentine ant (Linepithema humile) is one of the most destructive invasive ant species around the world. Conventional spray and bait strategies are among the common practices used to control Argentine ants in urban settings. Because of current concerns about environmental contamination and non-target impact by the insecticides, however, there is a greater need for better techniques which would allow us to accomplish better control with less amount of insecticide applied into the environment. Several behaviors of Argentine ant have important implications for the better use of insecticide, and studies implicate that some of these behaviors potentially can be exploited to develop better pest management techniques. First, the efficacy of insecticide application can be improved by maximizing horizontal transfer of the insecticide. Some insecticide has greater degrees of horizontal transfer among individuals of ants via physical contact such as mutual grooming and necrophoresis (dead-carrying behavior). Second, a novel bait station that is referred to as Virtual Bait Station is developed by exploiting mass recruitment behavior to aqueous sugar bait. In the Virtual Bait Station, the sugar water bait does not contain insecticide, but a non-repellent insecticide deposit is placed around the bait, so that ants expose themselves while foraging and recruiting to the bait. Third, efficacy and target specificity of existing control methods for pest ants might be improved by exploiting the target species' innate trail-following behavior, while simultaneously providing environmentally and economically favorable integrated pest management strategies. Specific application of the ideas and future improvement will be discussed.

Urban pest ants of South East Asia and their management

Chow-Yang Lee
Universiti Sains Malaysia, Malaysia

Urban pest ants are becoming an increasing important group of urban pests in South East Asia. Important indoor and outdoor species of pest ants include Monomorium pharaonis, Tapinoma melanocephalum, Monomorium destructor, Monomorium floricola, Anoplolepis gracilipes, Pheidole sp. and Paratrechina longicornis. Until recently, the management of pest ants in South East Asia has always relies on the use of insecticides especially from the pyrethroid class, in the form of residual sprays. Recently, baiting becomes a popular mode of ant control. In this presentation, discussion will be made on the common species of urban pest ants of South East Asia, pest management options and the underlying challenges.

Native invasive ants: A novel evolutionary trend in the age of global change

Grzegorz Buczkowski
Purdue University, U.S.A.

Disturbance resulting from urbanization is a leading cause of biotic homogenization worldwide. Native species are replaced with widespread nonnative species and ants are among the world's most notorious invaders. To date, all documented cases of ant invasions involve exotic introduced species that are spread around the world by human-mediated dispersal. I investigated the effect of urbanization on the evolution of invasive characteristics in a native ant species, the odorous house ant, Tapinoma sessile (Say). Colony social structure, life history traits, and the spatial pattern of nest distribution were compared by sampling T. sessile across a gradient of three distinct habitats: natural, semi-natural, and urban. Results demonstrate a remarkable transition in colony social and spatial structure and life history traits between natural and urban environments. In natural habitats, T. sessile colonies are comprised of small, monogyne (single queen), and monodomous (single nest) colonies. In urban areas, T. sessile often exhibit extreme polygyny and polydomy, form large supercolonies, and become a dominant pest. Results also suggest that urban T. sessile colonies may have a negative impact on native ant abundance and diversity. In the natural environment T. sessile coexisted with a wide array of other ant species, while very few ant species were present in the urban environment invaded by T. sessile. Habitat degradation and urbanization can lead to extreme changes in social and spatial colony structure and life history traits in a native ant species and can promote the evolution of invasive characteristics such as polygyny, polydomy, and supercolonial colony structure.

The perspective of red imported fire ant control in Taiwan: past, present, and future

Rong Nan Huang[1], Chin Cheng Yang[2], Cheng Jen Shih[3], Wen Jer Wu[4]

[1]National Taiwan University, Taiwan, [2]National Taiwan University, Taiwan, [3]National Taiwan University, Taiwan, [4]National Taiwan University, Taiwan

The red imported fire ant (RIFA), Solenopsis invicta, an exotic invasive species that was inadvertently introduced into Asia-Australian regions from USA in early 21st century, was reported in Taiwan in 2003. The initial infestation by RIFA is estimated up to 50,000 ha with most of colonies are found in one of two main counties (Taoyuan and Chiayi). The distribution of S. invicta in Taiwan reveals its invasive nature that the fire ant invasion is associated with global travel and transportation given that the main international airport is located in Taoyuan and that Chiayi harbors one of largest nursery stock industry in Taiwan. To eradicate this pest ant species, the National Red Imported Fire Ant Control Center (NRIFACC) was then launched in 2004 to conduct the surveillance, monitoring, public education, movement restrictions and chemical treatment. As estimated, approximately 23 million USD has been invested in this program in Taiwan since 2004, and infestation in Chiayi seems to be reduced in size substantially but not Taoyuan. The gradual spread of fire ants in Taoyuan indicates the long-term containment might be an appropriate strategy to manage ants there, considering the size of infested area and financial pressure due to tight budget. Hot spot treatment in core area, along with bait broadcast in outlier area, is therefore the main control scheme in North Taiwan this year. In addition, other control agents (e.g., biological control by nature enemies) are now under evaluation and may incorporate into future control/eradication program.

Advancements in baiting for management of pest ants: *Camponotus* spp *Liometopum* spp and *Tapinoma sessile*

Laurel Dianne Hansen
Spokane Falls Community College, U.S.A.

Structurally damaging ants occurring in the northern tier of states in the United States and Canada are carpenter ants, Camponotus spp., and in western United States and Canada, velvety tree ants, Liometopum spp. Tapinoma sessile, is also a major nuisance pest occurring in these areas. These species from two different subfamilies differ in biology and behavior but both feed on honeydew, homopteran insects, and other insects. Because of the similarity in feeding requirements, baiting strategies for these ants have proven effective in laboratory and field trials in recent years with baits formulated as gels, granulars, liquids, and in containerized stations. Consumer perception that baits are more environmentally friendly than other management strategies has encouraged the use of baits by professional technicians. Time required by technicians in application and monitoring baits has been reduced with the development of gels that are effective for several weeks, remain acceptable to foraging ants, and can be placed along foraging trails in concealed locations. In large colonies, liquid baits can be dispensed in larger volumes for continuous feeding. Gel and liquid baits are also acceptable early in the season when ants are overwintering in structures and attracted to environments with moisture.

Recent development in bait and trap technologies for yellow jacket control

Dangsheng Liang
Apex Bait Technologies, Inc., U.S.A.

Yellow jackets are important urban pests worldwide causing human suffering as well as ecological damages. There is a long history of attempt to develop a bait for their control but such efforts have not produced a marketable product. Trapping is currently the most popular control method but it fails to significantly suppress yellow jacket population level. Recently, we have initiated studies to develop bait and trap technologies for more effective yellow jacket control. We have developed a shelve stable ready-to-use yellow jacket bait that is highly attractive and palatable. Preliminary study found that using the bait containing an active ingredient resulted in a significant population reduction in the field.

Preliminary studies on the development of a liquid bait for bed bugs

Alvaro Romero
New Mexico State University, U.S.A.

Recently, the bed bug, Cimex lectularius L. (Hemiptera: Cimicidae), has re-emerged as a serious and growing problem, not only in North America, but globally. Today the mainstay for bed bug control is limited to the use of insecticide sprays based mainly on pyrethroids. However, recent laboratory studies reported that some bed bug populations have become highly resistant to this group of insecticides. Failure to eliminate resistant bed bugs could be a contributing factor for the spread of this pest. Therefore, alternative effective methods for bed bug control are of great importance. Here we explained the concept of a liquid bait system against bed bugs and the different steps that are being carrying out for its development. Progress toward this goal includes identification of phagostimulants and evaluations of oral toxicity of non-pyrethroid insecticides to bed bugs. The development and use of these technologies could play an important role in reducing human suffering caused by bed bugs, reducing insecticide applications, and minimizing economic losses associated with infestations.

Exploiting host molecules to augment the virulence of mycoinsecticides

Yanhua Fan[1], Dov Borovsky[2], Chloe Hawkings[3], Roberto M. Pereira[4], Almudena Ortiz-Urquiza[5], Engin Kilic[6], George Casella[7], Nemat O. Keyhani[8]

[1]Southwest University, China, [2]University of Florida, U.S.A., [3]University of Florida, U.S.A., [4]University of Florida, U.S.A., [5]University of Florida, U.S.A., [6]University of Florida, U.S.A., [7]University of Florida, U.S.A., [8]University of Florida, U.S.A.

Mosquitoes and fire ants represent two of the world's most important pest problem challenges, whose control remains elusive by current chemical pesticide or other means. Biological control by insecticidal fungi is a promising tool in suppressing insect populations; however their low virulence represents a major obstacle to their effective use. We report two examples of a novel approach to insect control, in which expression of host molecules in an insect pathogen was exploited for selective augmentation of virulence. First, expression of the yellow fever mosquito Aedes aegypti trypsin modulating oostatic factor (TMOF) by the entomopathogenic fungus Beauveria bassiana increased fungal toxicity towards mosquito adult and larvae. Larval development was stunted due to anorexia and adult fecundity was reduced because of inhibition of blood digestion. Increased fungal virulence was Aea-TMOF specific; expression of the grey flesh fly Neobellieria bullata (Neb)-TMOF in B. bassiana did not increase toxicity towards mosquitoes and Aea-TMOF expressing strains did not show increased virulence towards flesh flies. Second, expression of the fire ant pyrokinin β-neuropeptide (β-NP) by B. bassiana increased fungal virulence towards fire ants, but did not affect virulence towards the lepidopteran, Galleria mellonella. Ants killed by the β-NP expressing fungus were disrupted in the removal of dead colony members, i.e. necrophoretic behavior. Furthermore, synthetic C-terminal amidated β-NP but not the non-amidated peptide had a dramatic effect on necrophoretic behavior. These data link chemical sensing of a specific peptide to a complex social behavior. The described strategy can be exploited to increase the potential of biological

[1]Sumitomo Chemical, Japan, [2]The University of Tokyo, Japan, [3]The University of Tokyo, Japan, [4]The University of Tokyo, Japan, [5]The University of Tokyo, Japan, [6]The University of Tokyo, Japan, [7]Hokkaido University, Japan, [8]Shin-Etsu Chemical, Japan, [9]Earth Biochemical, Japan, [10]Japan Wildlife Research Center, Japan

Ants are significant urban pests. Currently, control of pest ants relies mainly on insecticidal baits. However, insecticidal baits cannot provide real solution for some species, due to rapid recovery of population. We have tried to control the invasive Argentine ant Linepithema humile in Japan using synthetic trail pheromone. In ants, trail formation via trail pheromone is an important social behavior that enables efficient foraging and migration. Here I present our five main results and propose two novel approaches for ant management, i.e., foraging suppression and migration inhibition via disruption of trail-following behavior. 1) Trails of Argentine ants were disrupted when a high dose of synthetic trail pheromone was dispersed in the habitat atmosphere. The effect was species-specific. 2) The trail disruption led to reduced recruitment of Argentine ants to food sources. 3) Hoping that the reduced recruitment of the ants to food sources leads to suppression of colony growth rate, a year-long treatment with synthetic trail pheromone dispensers was conducted on 100 m2 plots of house gardens in an urban district of Iwakuni City, western Japan, but no clear control effect was obtained within the plots. 4) However, combined treatment with synthetic trail pheromone dispensers and insecticidal baits effectively suppressed ant populations within the 100 m2 plots. 5) Under the strategy of inhibiting ant migration with synthetic trail pheromone and suppressing ant population with insecticidal bait, Argentine ants were successfully eliminated from most of the 6.7-ha habitat range in Yokohama Port, eastern Japan.

Teaching sustainable techniques for German cockroach control in low-income, multi-unit housing

Dini Miller[1], Tim McCoy[2]
[1]*Virginia Tech, U.S.A.*, [2]*Virginia Tech, U.S.A.*

Low-income multi-unit housing is continuously plagued with large populations of German cockroaches. With so many effective bait products (and negligible cockroach resistance to baits), how do these populations continue to exist? One reason is that low-income facilities are often mandated to hire the lowest bidder for pest management contracts. The break-even cost for pest control companies in the US is ~$1.00 /minute of technician time. In cases where the pest control contract for the apartment community averages $6/unit, the technician must spend < 6 min in a single apartment to make any profit for his company. In highly unsanitary and cluttered environments, the technician struggles to find places where gel bait can be applied without contaminating non-labeled surfaces. Consequently, the technician does not have the time (or space) to put out enough bait to reduce the cockroach population. In highly infested units in Richmond VA, cockroach populations in apartment units were monitored prior to their quarterly pest control service in June 2011. Three weeks after treatment, the same units were monitored again, only to find that the populations had doubled in size. We hypothesize that the populations were so large, and the amount of bait applied was so small, that the cockroaches annual summer growth cycle was completely unaffected by the pest control service. The purpose of this study was to develop an application method where large amounts of gel bait (60-90 g; enough to impact the cockroach population within a unit), could be placed in a very short period

Trojan Horses for target specific urban pest management

Claudia Husseneder[1], Amit Sethi[2], Lane D. Foil[3]

[1]Louisiana State University Agricultural Center, U.S.A., [2]Louisiana State University Agricultural Center, U.S.A., [3]Louisiana State University Agricultural Center, U.S.A.

Subterranean termites are dependent on protozoa in the hindguts of workers to efficiently digest wood. Using the Formosan subterranean termite as a model we are developing alternative systems for termite control with reduced use of chemicals by employing a technique known as paratransgenesis. Paratransgenesis uses genetically engineered microorganisms as "Trojan Horses" to express foreign genes in host organisms bypassing the host's defenses. We engineered yeast to express lytic peptide coupled to a ligand. Lytic peptides are part of the innate immune system of insects and kill microorganisms but are fairly safe for higher eukaryotes. The ligand specifically binds the lytic peptide to the protozoa in the termite gut, which are important for cellulose digestion. The expressed ligand-lytic peptide kills protozoa and the termites starve. However, the addition of the ligand makes the lytic peptide less toxic for non-target cells, such as bacteria or gut tissue cells. The engineered yeast was freeze-dried, incorporated in cellulose bait and fed to termites in the lab. Yeast was shown to survive and increase in numbers in the termite gut. Yeast was also transferred from termites which fed on the yeast bait to termites which did not feed on the bait. Protozoa in the termite gut died within three weeks and all termites died within five weeks after feeding on the bait. Since traditional biological control methods usually show little success in the field due to the effective defense mechanisms in social insects, paratransgenesis is a promising technology for enhanced microbial control.

Advances in drywood termite detection, a comparative review

Vernard Richard Lewis
University of California Berkeley, U.S.A.

Advances in drywood termite detection, a comparative review. Vernard R. Lewis University of California, Berkeley Department of Environmental Science, Policy and Management 137 Mulford Hall #3114, Berkeley, CA 94720-3114. Abstract -I will review and present published findings on advances in drywood termite detection. My comparisons will include termite feeding devices, motion detectors, infrared, and X-ray technologies. Recent published efficacy testing on canine detection will also be included. I will also highlight those studies that include efficacy testing of devices when drywood termite infestations are hidden from view and behind wall coverings. Also critical to the detection of drywood termites are what factors constitution a drywood termite colony and the frequency of colony feeding. Currently, the definition of a drywood termite colony is based on location; infested boards that are widely separated are assumed to contain different colonies. There is no biological definition. Regarding frequency of colony feeding, until recently it was unknown. Molecular genetics of workers conducted in collaboration with North Carolina State University and chemical analyses of fecal pellets conducted in collaboration with the USDA Forest Service were able to separate colonies of drywood termites and could provide a measure of successful or failed treatments. Additionally, I will review the recent findings that drywood termites have uneven feeding patterns throughout a day and during the year. Finally, the combination of several detection devices used in tandem with knowing the diurnal and seasonal pattern of drywood termite feeding will aid in the development of future detection schemes and devices.

German cockroach (Dictyoptera: Blattellidae) IPM: A cost / benefit analysis

Dini Miller[1], Frank Meek[2]
[1]*Virginia Tech, U.S.A.,* [2]*Orkin Pest Control, U.S.A.*

The long-term costs and efficacy of two treatment methods for German cockroach control were compared in the public housing environment. The "traditional" treatment consisted of monthly baseboard and crack and crevice treatment (TBCC) using spray and dust formulation insecticides. The integrated pest management treatment (IPM) involved vacuuming, followed by monthly or quarterly applications of baits and insect growth regulator (IGR) devices. Technician time and the amount of product applied were used to measure cost in both treatments. Trap catch (24h) was used to determine treatment efficacy. The cost of the IPM treatment was found to be significantly greater than the traditional treatment at the initiation of the test. However, to evaluate the long-term costs of the two treatments over the entire year, technician time and product quantities were averaged over all units treated within the 12-mo test period (total 600 units per treatment). The average per unit cost of the IPM treatment was significantly greater ($4.06) than that of the TBCC treatment ($1.50). Although the TBCC was less expensive than IPM, it was also less effective. Trap catch indicated that populations in the TBCC treatment were static for the first 5 mo of the test and then had a threefold increase during the summer. Cockroach populations in the IPM treatment were significantly reduced from an average of 24.7 cockroaches per unit before treatment to an average 3.9 cockroaches per unit by month 4. The cockroach populations in the IPM treatment remained suppressed for the remaining 8 mo of the test.

Effectiveness of baiting and IPM for managing German cockroaches in apartment buildings

Changlu Wang
Rutgers University, U.S.A.

Cockroach gel baits are dominant products for managing German cockroaches in the U.S. since the late 1990's.They provide high level of German cockroach population suppression with much less environmental impact than liquid or dust insecticides. We evaluated the effectiveness of baiting alone method for German cockroach control using baits containing hydramethylnon, fipronil, dinotefuran, and indoxacarb in multi-unit apartment buildings occupied by low income people. These results were compared with IPM programs that incorporating sanitation, monitoring, decluttering and baiting. Results show both baiting alone and IPM can successfully control German cockroach populations. IPM provided more sustainable control. Concerns of bait aversion development will be discussed.

Insecticide resistance and its underlying mechanisms in the German cockroach

Chow-Yang Lee
Universiti Sains Malaysia, Malaysia

Heavy reliance and high frequency of insecticide usage have led to the development of insecticide resistance in the German cockroach. Since 1952 where the first case of insecticide resistance in the German cockroach was reported in Corpus Christi, Texas, USA, numerous cases of resistance have since been reported. Resistance to insecticides in the German cockroach is no longer limited to the conventional insecticide groups such as chlorinated hydracarbon, organophosphates, carbamates and pyrethroids. More recently, low to moderate levels of resistance to compounds from newer groups such as neonicotinoid, oxadiazine and phenyl pyrazole have been detected. In this paper, discussion will be made on the recent cases of insecticide resistance status in the German cockroach, and the underlying mechanism of resistance found in these collected populations.

History and development of cockroach bait technology and future innovations

Mark A. Coffelt
DuPont Crop Protection, U.S.A.

Cockroach baits have had a long and successful history in urban pest control and they have become an important component of integrated pest management programs throughout the world. In order to attract cockroach species to feed on baits, they must have an attractive, highly palatable matrix. The key to success is developing cockroach bait matrices that are readily fed upon by cockroaches, even with competing food resources that may be available. Bait aversion is a potential issue with the bait matrice. In addition, the active ingredient must be nonrepellant, have a slow or delayed mode of action, cause mortality at low doses, and allow for secondary mortality through horizontal transfer of the bait. New active ingredients, matrices, inerts, delivery devices, and other innovations are driving cockroach bait technology to a new standard. The future of cockraoch integrated pest management with cockroach baiting appears to be bright, as new technology is being developed to constantly improve cockroach control in the urban environment.

Bait aversion in the German cockroach

Nonggang Nick Bao
Bayer, China

Baits have been the preferred and dominant formulation of choice for performing German cockroach control services since the 1980s. German cockroach control failures due to behavioral aversion to baits, rather than resistance to insecticides, were first reported in the early 1990. Behavioral and feeding aversion to glucose was documented as the underline mechanism. Less than a decade later, German cockroach control failures were again reported from the field to the cockroach gel baits that contain no glucose. Rotations between major commercially available gel baits did not reverse control failures. Researchers identified and speculated fructose and other substances as the culprits, responsible for the resurgence of German cockroach infestations. The author reviewed the history of bait aversion, the differences between insecticide resistance and bait aversion, the feasibility of bait rotation strategy, and research finding on underlying mechanisms and innovative solutions. The author also provided insights and recommendations on cockroach bait aversion researches and management, as part of an effective cockroach IPM program.

Green pest management approaches against cockroaches

Arthur G. Appel[1], Steven R. Sims[2], Marla J. Eva[3]
[1]Auburn University, U.S.A., [2]BASF, U.S.A., [3]Auburn University, U.S.A.

Green pest management includes the use of least toxic and preferably organic insecticides together with application methods that reduce the use of insecticides and limit human exposure. In addition, cultural control measures such as habitat modification and changes in human behavior can be integrated to provide rapid and sustainable cockroach management. For peridomestic species such as the Asian and smokybrown cockroach, landscape mulch preference studies have revealed locations for either targeted insecticide application or modifications of the landscape. Light attraction studies have revealed the utility of yellow 'bug lights' for providing light while not attracting cockroaches. Modifications of human behaviors such as altering landcsape watering schedules and removing pet food immediately after feeding help to reduce cockroach resources. Removal of outdoor debris and objects in the landscape also aid control measures. Domiciliary cockroach species such as the brownbanded and German, also have prefered habitats and resources within apartments and homes. Alteration, modification, and elimination of these significantly aid cockroach management. Use of least toxic insecticides is critical indoors and in close proximity to humans and pets. Insecticidal baits either enclosed in child-resistant exposure stations or gel and paste formulations applied in cracks and crevices provide rapid reductions of populations. Targeted direct contact use of aerosolized essential oil formulations is effective, but there is no toxic residual. Combining 'clean-out' applications of essential oils with longer term protected baits is an effective management system. Least toxic insecticides used in conjuntion with habitat modification and resource elimination provides superior cockroach management.

Survey of bed bug infestation in Southeast Asia and research updates

Chow-Yang Lee
Universiti Sains Malaysia, Malaysia

Bed bug survey carried out in Malaysia, Singapore and Thailand revealed that the tropical bed bug Cimex hemipterus (Fabricius) is the predominant species in Southeast Asia. Cimex lectularius was found in the northern region of Thailand. Bed bug infestations were common in hotels and public accommodations when compared to residential premises. The three most common locations of infestation within an infested premise were the bedding (31.09%), the headboard (30.25%), and cracks and crevices surrounding the baseboard, wall, or floor (23.53%). In this presentation, discussion will be made on the results of the bed bug surveys in this region, as well as the recent findings on C. hemipterus biology and ecology.

Bed bug infestation and management in Shenzhen, Guangdong province, China

Xiujun Wen[1], Changlu Wang[2], Xingwen Li[3], Zengyu Huang[4], Tao Ma[5]

[1]South China Agricultural University, China, [2]Rutgers University, U.S.A., [3]South China Agricultural University, China, [4]South China Agricultural University, China, [5]South China Agricultural University, China

Nationwide Four-Pest Elimination campaigns (bed bugs being one of the targeted pests) were implemented in China 1970 to the late 1980s. These campaigns succeeded in eliminating bed bug infestations in most communities. Although international and domestic travel has increased rapidly in China over the past decade, there have only been sporadic new infestations reported in recent years. Shenzhen (a city near Hong Kong) experienced significantly higher number of bed bug infestations than other cities. We investigated the prevalence of bed bug infestation and management in Shenzhen through on site inspection and telephone interviews from September 2011 to March, 2012. Surveyed communities included Health and Epidemic Prevention Stations, pest control companies, schools, hospitals, factories and residences. Only tropical bed bug, Cimex hemipterus (F.) was found in the surveys. The common bed bug, Cimex lectularius L. was not identified in this survey, though it was reported that the common bed bug was the dominated species in Shenzhen in the literature. This study indicates that bed bug infestation in Shenzhen dramatically decreased following the campaigns from 1970 to the late 1980s, but remained active in factory dormitories and old rental houses where crowded and poor living conditions were present.

Bed bug management practices in the U.S.A.

Ronald Deane Harrison
Orkin, LLC, U.S.A.

Abstract 2012 ICE 12-4 Bed bug management practices in the U.S.A. Around 2000 AD, bed bugs started appearing as a minor pest in the United States. Traditional spraying of baseboards has been replaced by more targeted pest specific methods of treatment. These IPM methods do not seem to work well for bed bugs. Experienced technicians reverted back to base board type applications. These treatments were not successful either. During the last 10 years, many treatment methods have been tested. Bed bugs have shown resistance to dust and liquid formulated pyrethroids. Pyrethroid only products have been replaced by a different class or combination of pesticide chemistries. Heat is another treatment technique which has been incorporated into bed bug service. Fumigation has been implemented on a limited basis. Education and cultural techniques have been implemented with limited success. Pest control companies in the United States that follow strict treatment protocols are successful in controlling bed bugs, but services that are not thorough allow for pesticide resistance and for individual bed bugs to remain. Certain parts of society do not treat for bed bug infestations thus allowing bed bugs to spread.

Evaluation of sustainable methods for bed bug control in low-income facilities

Dini Miller[1], Molly Stedfast[2]

[1]Virginia Tech, U.S.A., [2]Virginia Tech, U.S.A.

The common bed bug, Cimex lectularius (L.) is establishing itself as the most economically important pest in the United States. Arguably, the low-income, multi-unit housing industry has been the most financially vulnerable to infestations of this pest. Several states have passed legislation identifying apartment owners as being financially responsible for bed bug eradication. However, bed bug management is a very time consuming process. A highly infested apartment complex can take several months to treat, with new bed bug introductions occurring throughout the treatment process. In the US, apartment management companies have paid anywhere from $8,000 to more than $100,000 in a single year for bed bug treatment. To manage the costs of bed bug remediation, proactive bed bug prevention measures need to be adopted. However, bed bug prevention methods for use in multi-unit housing have not been developed or evaluated for efficacy. The objective of this study was to develop, and evaluate the efficacy of a bed bug prevention protocol in the field. Specifically, we intended to determine if the protocol (which included resident training, vacuuming, applications of diatomaceous earth, installation of passive monitoring devices, and the building of an on-site heat chamber) could be successfully implemented by apartment facilities staff after being trained by certified applicators. Next, we wanted to determine if the implementation of the protocol would reduce the number of infestations and subsequent remediation costs. In 2012, a bed bug prevention protocol was implemented in a 120-unit government subsidized facility located in Harrisonburg, VA.

Chemical ecology of bed bugs: Practical applications

Changlu Wang[1], Narinderpal Singh[2], Richard Cooper[3]

[1]Rutgers University, U.S.A., [2]Rutgers University, U.S.A., [3]Rutgers University, U.S.A.

Understanding the host-finding behavior of bed bugs is utmost important in designing effective monitoring tools and for controlling bed bugs. A large array of chemicals are found to illicit bed bug responses in laboratory assays. Yet, their practical use in bed bug monitoring was rarely investigated. We evaluated the effect of > 12 chemical lures and their combinations on bed bug monitors in the laboratory. Then we investigated the attractiveness of a chemical lure mixture in naturally infested apartments. Many of the suggested chemicals that affect bed bug behavior in laboratory evaluations did not exhibit values in bed bug monitoring. Nevertheless, an inexpensive lure mixture was found being able to significantly increase the bed bug monitor efficacy when used alone or in combination with carbon dioxide (CO2). It is clear that chemical lures are important behavioral modulators in a short range (i.e. < 1 m) whereas CO2 is the most important attractant for initiating bed bug foraging activities. The results also demonstrate the complex nature of the bed bug responses to chemical lures. Their responses are at least affected by the bed bug hungry levels, distance of bed bugs from the lure source, air flow rate, concentration of lure in the air, and presence/absence of a human host. Further investigations on bed bug responses to various lures will help develop more effective bed bug monitors that can be used to increase the monitor efficacy and reduce monitoring costs.

Refining non-chemical control tactics against the bed bug, *Cimex lectularius*

Stephen A. Kells[1], Joelle F. Olson[2], Michael J. Goblirsch[3]
[1]*University of Minnesota, U.S.A.,* [2]*University of Minnesota, U.S.A.,* [3]*University of Minnesota, U.S.A.*

The resurgence of bed bugs in society and initial difficulties encountered with insecticide applications against this pest has resulted in a number of non-chemical controls being developed that either replace or supplement traditional treatments. Use of extreme temperatures against insect infestations is not a novel approach, but development of commercial equipment and improved deployment of existing devices has increased the use of non-chemical controls against this pest. There are several challenges when applying heat or freezing temperatures to control of bed bugs. With high temperature treatments, determining critical temperatures and investigating bed bug behavioral responses have been important considerations. For control using freezing temperatures, understanding how freeze physiology of bed bugs affects required temperature and time of exposure is important for ensuring maximum efficacy in the shortest time possible. Overcoming these challenges make non-chemical treatments more practical by minimizing costs of control through the reduction of energy use and labor required for successful control. Reducing the disruption to people's lives and minimizing the risk of damage caused by these treatments also help to increase adoption of non-chemical control methods. Mainstream use and the experience gained from applying these technologies provide an opportunity to expand non-chemical control methods against other pests in the urban habitat.

Importance of low level detection and the role of monitoring in bed bug management

Richard Cooper[1], Changlu Wang[2], Narinderpal Singh[3]
[1]Rutgers University, U.S.A., [2]Rutgers University, U.S.A., [3]Rutgers University, U.S.A.

Bed bugs are a major pest in many parts of the world. The ability to detect bed bugs in low numbers is essential in managing the costs associated with management efforts and reducing spread. Failure to detect bed bugs at the onset can result in well-established infestations that are costly to control and promote spread. Similarly, failure to detect bed bugs during the terminal end of a treatment effort can result in premature termination of the control program, population rebound and spread. We used a bed bug intercepting device to evaluate population distribution in apartments, to confirm bed bug elimination after treatments, and to evaluate the bed bug population dynamics in lightly infested (< 10 bed bugs in monitors) apartments. This device was more effective in detecting bed bugs compared to visual inspections in previous studies. We found that 50-90% of the bed bugs were consistently captured away from sleeping and resting areas (beds and upholstered furniture). Bed bugs are more mobile than previously believed and the presence of low numbers of bed bugs is easily missed by visual inspections alone. Low level infestations failed to become established in at least 50% of apartments monitored when left untreated. After the infestations were declared eliminated by the pest control technicians, over 50% of them were still found infested. The study demonstrates the importance of proper placement of monitors for detecting bed bugs, long range movement of bed bugs in structures, and intervention strategies for bed bugs when their numbers are low.

Recent progress in bed bug research in the USA

Alvaro Romero
New Mexico State University, U.S.A.

Prior to the mid-twentieth century bed bugs, Cimex lectularius L., were fairly common in the USA and other countries. However, after the advent of powerful synthetic insecticides such as DDT in the 1940's, their prevalence greatly decreased, particularly in developed countries, and only sporadic infestations were detected, primarily in dwellings with high occupant turnover and questionable sanitation conditions. Over the last ten years however, a general global resurgence of bed bugs has been reported in Asia, Europe, North America, and Australia. Unlike in the past, bed bugs have been reported in a variety of places including single-family dwellings, apartments, hotels, health care facilities, laundries, theaters, college dormitories, and means of transportation. Bed bug infestations are expected to increase in the coming years, presenting many challenges to the pest control industry and the society in general. Basic and applied knowledge about this urban pest is extremely limited compared to other major pest insects. This presentation shows results of research designed to provide not only practical information for bed bug control, but also to begin to resolve the knowledge vacuum that surrounds this pest. What follows is updated information about locomotor activity in bed bugs, feeding behavior, sublethal effects of insecticides, pyrethroid resistance, synergism of pyrethroids, and evaluation of non-pyrethroid insecticides. The implications of these findings on the management of this pest will be discussed.

Beating the bugs: The australian approach to combating the bed bug resurgence

Stephen Lindsay Doggett
Westmead Hospital, Australia

Australia, particularly since the year 2000, has undergone a massive resurgence in bed bug infestations from both the common (Cimex lectularius L.) and tropical (C. hemipterus F.) species. A three point strategy was implemented to combat the rise: the development of an industry standard that promotes 'best practice' pest management, education of stakeholders in 'best practice', and research to evolve 'best practice'. An industry standard that encompasses IPM in bed bug management, 'A Code of Practice for the Control of Bed Bug Infestations in Australia' (CoP), was first developed in 2006 and has been regularly updated with advances in management technologies such that the current edition is the eighth version. This standard has been adopted by other pest management industries and formed the basis of the European bed bug management standard. To encourage education of stakeholders in 'best practice', the CoP is available free from a dedicated web site, www.bedbug.org.au. A curriculum was developed, based on the CoP, and the ensuing course has been used to train stakeholders in bed bug eradication. Pest managers who successfully complete the course are listed on the above bed bug web site. To assist those industries who provide accommodation, a 'Bed Bug Management Policy & Procedural Guide for Accommodation Providers', has been developed and is also freely available. Various research projects have been undertaken, from non-chemical control investigations to insecticide efficacy, with the results used to develop the industry standard. These strategies will continue to be refined while bed bugs remain problematic.

Apolipophorin-III (ApoLp-III) is known to play an important role in lipid transport and innate immunity in lepidopteran insects. However, there is no evidence of involvement of ApoLp-IIIs in the immune responses of dipteran insects such as Drosophila and mosquitoes. We report the molecular and functional characterization of An. gambiae apolipophorin-III (AgApoLp-III). Mosquito ApoLp-IIIs have diverged extensively from those of lepidopteran insects; however, the predicted tertiary structure of AgApoLp-III is similar to that of Manduca sexta (tobacco hornworm). We found that AgApoLp-III mRNA expression is strongly induced in the midgut of An. gambiae (G3 strain) mosquitoes in response to Plasmodium berghei infection. Furthermore, immunofluorescence stainings revealed that high levels of AgApoLp-III protein accumulate in the cytoplasm of Plasmodium-invaded cells and AgApoLp-III silencing increases the intensity of P. berghei infection by five fold. There are broad differences in the midgut epithelial responses to Plasmodium invasion between An. gambiae strains. In the G3 strain of An. gambiae AgApoLp-III participates in midgut epithelial defense responses that limit Plasmodium infection.

The mosquito STAT pathway and its role in *Plasmodium* development

Lalita Gupta[1], Kuldeep Gupta[2], Mithilesh Kajla[3], Rini Dhawan[4], Sanjeev Kumar[5]

[1]Birla Institute of Technology & Science, India, [2]Birla Institute of Technology & Science, India, [3]Birla Institute of Technology & Science, India, [4]Birla Institute of Technology & Science, India, [5]Birla Institute of Technology & Science, India

Signal transducers and activators of transcription (STAT) family of transcription factors are evolutionary conserved and participate in immunity in response to cytokine signaling. In most of the insects, single STAT gene has been reported; however in Anopheles gambiae gene duplication takes place and ancestral STAT-A gene is regulated by intronless STAT-B. Plasmodium infection induces mRNA expression of SOCS (Suppressor of cytokine signaling) and NOS (nitric oxide synthase). AgSTAT-A silencing reduces the expression of NOS and SOCS suggesting that these genes are regulated by the STAT pathway. The AgSTAT-A pathway mediates a late phase anti-Plasmodial response through the induction of NOS which eventually reduces oocyst survival in An. gambiae. The STAT pathway is conversed in mosquitoes and regulates virus, bacteria and Plasmodium infection. We are exploring further the role of STAT pathway in Indian mosquitoes (An. stephensi) and characterizing the downstream signaling molecules which regulate innate immunity against various pathogens.

Mosquito gut is not only involved in digestion but also considered to be an immune organ because it encounters foreign antigens present in the ingested food. Gut immunity is under the regulation of some specific molecules which control the effectiveness of immune system against selective foreign antigens. We found that mosquito peroxidases help in creating a barrier between engulfed antigens and gut immunity to suppress their direct encounter. This barrier system modulates the mosquito immunity to maintain low-immunity zone in the gut for the proliferation of commensalisms bacteria and Plasmodium takes an advantage of this environment to complete its development inside the gut lumen. Manipulation of these immunimodulators may be promising to effectively block malaria parasite development.

A selective barrier in whitefly associated with vector-specific transmission of Tomato yellow leaf curl China virus

Jing Wei
Zhejiang University, China

Tomato yellow leaf curl China virus (TYLCCNV) is known to be transmitted by the whiteflies in the Bemisia tabaci species complex in a circulative, persistent manner. Although virus circulation within B. tabaci has been well recognized, the specificity of virus circulation and transmission involved in different cryptic species of the B. tabaci complex remains largely unknown. Here we report that the invasive B. tabaci Mediterranean (MED) species cannot or only very poorly transmits TYLCCNV while the invasive B. tabaci Middle East-Asia Minor 1 (MEAM1) species can effectively transmit it. However, after continuous feeding on virus-infected plants, the relative levels of abundance of viral genomes in whitefly bodies between MED and MEAM1 were similar, suggesting that both species could ingest and retain TYLCCNV efficiently. Viral DNA tracing experiments indicated that TYLCCNV can cross the salivary glands of MEAM1 efficiently but not that of MED. Quantitative PCR indicated that virus abundance in salivary glands was 15 times higher in MEAM1 than in MED. Fluorescence in situ hybridization results revealed that the TYLCCNV transcripts were present in the midgut of these two species while viral DNA was found in the primary salivary gland of MEAM1 but not that of MED. This further demonstrates that the virus transmission route is blocked at the salivary gland cells in MED.

Increased insulin signaling in the midgut of *Anopheles stephensi* blocks development of the malaria parasite, *Plasmodium falciparum*

Michael A. Riehle[1], Vanessa Corby-Harris[2], Anna Drexler[3], Jenya Antonova-Koch[4], Nazzy Pakpour[5], Shirley Luckhart[6]
[1]University of Arizona, U.S.A., [2]University of Arizona, U.S.A., [3]University of Arizona, U.S.A., [4]University of Arizona, U.S.A., [5]University of Arizona, U.S.A., [6]University of Arizona, U.S.A.

Insulin and the insulin/IGF-1 signaling (IIS) cascade regulates lifespan and immunity in the mosquito Anopheles stephensi. Exogenous insulin from the vertebrate bloodmeal can stimulate IIS in the mosquito midgut, as can feeding the mosquito physiological concentrations of human insulin. Furthermore, these concentrations of insulin can significantly reduce the mosquito's lifespan. To further explore this phenomenon we engineered an active form of the insulin signaling molecule AKT into the mosquito genome under the control of the carboxypeptidase promoter. This resulted in midgut specific expression of the transgene, but surprisingly not bloodmeal specificity. Increased insulin signaling in the midgut led to a significant reduction in mosquito lifespan comparable to mosquitoes fed human insulin. When challenged with Plasmodium falciparum parasites, heterozygous transgenic mosquitoes had a 75-99% reduction in parasite load compared with non-transgenic siblings. More importantly, homozygous Akt mosquitoes were completely resistant to midgut invasion by the malaria parasite. The reduction in infection prevalence and parasite intensity, coupled with a reduction in lifespan results in a two pronged approach towards controlling malaria. Not only would the mosquito transmit far fewer parasites, but those mosquitoes will not survive as long following the extrinsic incubation period, resulting in fewer infectious bites.

Community engagement practices and genetically-modified mosquitoes

Anthony A. James
University of California, U.S.A.

Novel technologies for public health applications are fostering analyses and inquiry of the roles of communities in research and what they can expect to receive in exchange for their participation. Community engagement activities addressing the results of these analyses are challenging for new scientific approaches, especially those based on controversial strategies and those in which some risks are poorly understood or determined. For many applications, no explicit body of community engagement knowledge exists from which researchers can derive guidance about approaches most likely to be effective in different contexts. Frameworks have been developed recently that provide starting points for broader discussions of community engagement in global health research, particularly as it relates to the development, evaluation, and application of new technologies. Experiences in a number of countries will be presented highlighting unique and common features, and lessons-learned.

Integrating ecological and anthropogenic mechanisms into a framework for advancing forensic entomology research

Sherah Lynnette VanLaerhoven
University of Windsor, Canada

Considerable research in forensic entomology has focused on patterns of insect arrival on bodies, however, few have examined what mechanisms drive these patterns. Without an understanding of these mechanisms, it is not possible to make predictions under different scenarios. However, the basic premise of forensic entomology is using the insect evidence to make predictions as to the associated time line. By changing how we think about the system, by incorporating ecological theory and putting our research into a framework of examining mechanisms, we can identify the critical mechanisms driving assembly. Both natural (ecological) and anthropogenic (man-made) mechanisms are important in death investigations and insect evidence, thus it is vital to not only explore these two categories of mechanisms individually, but also how they interact to drive arrival patterns of insect and the resulting insect evidence. Examples of research from my laboratory will illustrate the role of various ecological and anthropogenic mechanisms and their interaction in driving insect arrival patterns. By framing our research in this manner, we more rapidly identify the critical questions that will advance our field.

Estimating postmortem intervals from development of *Thanatophilus* (Silphidae) beetles

Martin Villet[1], Jaryd Ridgeway[2], John Midgley[3]

[1]Rhodes University, South Africa, [2]Rhodes University, South Africa, [3]Rhodes University, South Africa

Thanatophilus mutilatus is a carrion-feeding beetle that is endemic to South Africa. Specimens were individually reared through their entire life cycle at one of seven constant temperatures (15℃; 17.5℃; 20℃; 22.5℃; 25℃; 27.5℃ and 30℃), and the time they took to reach eight different development landmarks was recorded. Body length and body width were measured throughout the above-surface development stages. Individuals grew larger at lower temperatures but took longer to develop. Mortality was 90% at 27.5℃ and 100% at 30℃. Using major axis regression, a standard thermal summation model for predicting development was generated and compared with that of Thanatophilus micans. Thanatophilus mutilatus is a forensically important insect which fills the successional period between T. micans and Dermestes haemorrhoidalis, emphasising that even developmental data derived from sister species cannot be used as surrogate data for unstudied focal species in forensic cases.

Population genetics in forensic entomology

Christine J. Picard
Indiana University - Purdue University Indianapolis (IUPUI), U.S.A.

Blow flies (Diptera: Calliphoridae) display a variety of habits, however they are best known for their role in the decomposition of carrion. As yet, there are few studies of their population genetic structure, although such data could contribute to such fields as pest management, taxonomy, forensic entomology and veterinary medicine. Since changes in physiological responses due to geographic variation would theoretically have an underlying genetic component, the discovery of genetically distinct subpopulations would suggest that baseline data for forensic applications should be gathered from each subpopulation. Current research into population genetic methods has focused on using a haploid DNA marker (mitochondrial DNA) with some development into the use of microsatellite loci. My research led to the development of thousands of polymorphic DNA loci: amplified fragment length polymorphisms (AFLP). Population genetic data was collected for two common North American blow flies (Lucilia sericata and Phormia regina). Though the populations were panmictic over a wide geographic scale, individual samples of flies were not a random sample of the population, but rather consisted of a large number of related individuals. The reproductive status of females found gravid females also were related (more so than would be expected if dispersal was random), therefore related females are following the same odor plumes throughout a minimum of two carrion visits (one for a protein meal, and one for laying eggs). These data caution the experimental designs set in place for development studies, as samples of blow flies do not represent a random sample of the population.

Standards for high quality research on larval morphology of necrophagous flies

Krzysztof Szpila
Nicolaus Copernicus University, Poland

Larvae of flies are usually the most abundant colonizers of dead human bodies recovered in forensic investigations. Immature stages of flies are frequently collected in casework, but usually a sub-sample of eggs or larvae are reared to the adult stage to enable precise species identification. An alternative approach to identification is the use of molecular methods. However, classical methods of species identification of larval material based on an analysis of morphological characters remain an attractive option. Use of good identification keys supported by a detailed description of larval characters may be cheaper and faster than DNA analyses. Contemporary knowledge of the morphology of necrophagous flies is reasonably good in comparison to other groups of Diptera. Good descriptions are accumulating but many are superficial and provide insufficient useful information for taxonomic purposes. Morphological variability of larvae of necrophagous flies is reasonably low. The combination of available features is restricted mainly to small variations in the morphology of the cephaloskeleton, distribution of spines, position and shape of papillae on the anal division, number of lobes of anterior spiracles and position and shape of posterior spiracles. High quality standards in description of larval morphology should encompass: 1) proper killing and preservation techniques, 2) broad sampling according to population diversity, 3) suitable techniques of preparation for microscopic analyses, 4) detailed illustrative documentation of important structures, 5) statistical analysis of quantitative characters. Consistent abiding to the listed rules would result in providing identification keys that should be easily applicable even in poorly equipped laboratories.

Volatile compounds at initial decomposition as attractants for the blow fly, *Chrysomya megacephala* (Fabricius)

Kittikhun Moophayak[1], Kom Sukontason[2], Hiromu Kurahashi[3], Kabkaew L. Sukontason[4]

[1]Chiang Mai University, Thailand, [2]Chiang Mai University, Thailand, [3]National Institute of Infectious Diseases, Japan, [4]Chiang Mai University, Thailand

Flies in the Calliphoridae family are primary insect species that attracted to fresh cadavers. Like other necrophagous insects, they primarily use a volatile chemical cue emitted from decomposing organic matter that can orientate them to a corpse. To understanding the interaction between blow flies and initial decomposing chemical volatiles better, comparative attraction of chemical compounds emitted from fresh and 1-day tainted pork scrap were assessed against virgin and mated C. megacephala, a forensically important blow fly species in many parts of the world, including Thailand. Investigations using a wind tunnel bioassay revealed that 1-day tainted pork scrap had a significantly higher potential for luring virgin and mated flies than fresh products. No significant differences in attraction were found between virgin and mated flies to fresh and to 1-day tainted pork scrap. By analyzing with HS-SPME-GC-MS, a total of 13 compounds were identified. In 1-day tainted pork scrap, the predominant compounds were in the sulfur group (dimethyl disulfide, dimethyl trisulfide, dimethyl tetrasulfide and elemental sulfur), followed by organic acids, ammonia, carbon dioxide and indole. On the other hand, the compound obtained from the fresh product was mainly carbon dioxide, in combination with small amounts of ammonia, hydrocarbons, propanedioic acid and elemental sulfur. Based on these results, it is suggested that a larger number of virgin and mated C. megacephala are attracted to 1-day tainted pork scrap than fresh matter. The correlation between chemicals analyzed in this experiment and other compounds documented previously from human corpse and animal carcass is discussed.

Decomposers of carrion: Structural and functional relationships of micro- and macroorgansisms removing vertebrate carcasses from terrestrial ecosystems

Jennifer L. Pechal[1], Mark E. Benbow[2], Tawni L. Crippen[3], Aaron M. Tarone[4], Jeffery K. Tomberlin[5]

[1]University of Dayton Department of Biology , U.S.A., [2]University of Dayton Department of Biology , U.S.A., [3]Southern Plains Agricultural Research Center , U.S.A., [4]Texas A&M University Department of Entomology , U.S.A., [5]Texas A&M University Department of Entomology, U.S.A.

Carrion decomposition has primarily been attributed to invertebrate consumption, with little attention given to microbial communities. Invertebrate succession patterns and corresponding interactions have been documented for over 150 years. However, there has yet to be a study documenting abundance and succession patterns of bacterial communities during decomposition or relating this information to arthropod succession. Total genomic DNA was used to identify bacterial communities via 454-pyrosequencing. Distinct bacterial community successional trajectories were associated with carcass exposed to (ACC) and excluded from (EXC) invertebrates. By the fifth day of decomposition, Firmicutes was dominant (97%) on ACC carcasses while Proteobacteria (82%) was dominant on EXC carcasses. These data are the first to document bacterial community succession on carrion. A secondary objective was to assess microbial community function in response to carrion insect colonization using metabolic profiling. Significant metabolic profile changes occurred during decomposition. Microbial community metabolic function on carrion with insect access continuously decreased over decomposition thus, demonstrating the potential discriminatory power metabolic profiles have during decomposition. Overall, these data add to the knowledge of driving forces governing decomposition of carrion, provide the first information of bacteria colonizing and utilizing carrion, and their potential ecological interactions with necrophagous Diptera. This work provides a foundation of empirical data that may be useful to improve forensic estimations of how long a body has been exposed for colonization by arthropods, or the period of insect activity that is often similar to the minimum postmortem interval. Additionally, these data provide information about decomposition times preceding invertebrate colonization.

Recent studies on factors affecting larval development in forensically important Australian blowflies

James Wallman
University of Wollongong, Australia

It is well known that the development of carrion-breeding fly larvae is profoundly influenced by a range of variables, both abiotic and biotic. Such factors include the temperature both of the surrounding air and among the larvae themselves, the physicochemical composition of the substrate on which the maggots are feeding, and competition both within and between species. Recent research has focused on better defining the effects of these variables, with the particular aim of refining estimates of minimum time since death. This paper reports on the results of several novel projects devoted to investigating larval development in Australian blowflies: 1) relationship between maggot mass volume and larval growth: our studies have shown that the growth of larvae is positively correlated with the volume of their aggregation (as distinct from larval density); 2) using CT scanning to infer volumes of larval masses: we have revealed that volumes of maggot masses can be inferred from CT images, thus potentially assisting with estimating mass temperatures; 3) interspecific interactions among blowfly larvae: work to date suggests that such interactions may be more sophisticated than mere exploitative resource competition, thus questioning the applicability of developmental data from species monocultures; and 4) effects of methamphetamine on development: this ubiquitous recreational drug and its metabolites significantly influence fly growth, thus potentially affecting estimates of minimum death time in drug cases.

Three forensic insights from a reveiw of ecological succession on carrion

Martin Villet
Rhodes University, South Africa

A recent review of ecological succession on carrion provided new three insights. First, the guild structure of the insect community on carrion can be redescribed in a way that is more meaningful to forensic entomology. Second, the traditional description of decomposition in terms of stages is less useful to forensic entomology than a simple distinction between 'wet' and 'dry' phases of the succession process. Third, revised accounts of the guild structure and succession process that characterize the insect community of carrion allow a more mechanistic account of ecological succession in carrion that can enhance forensic entomology worldwide.

Welcoming Remarks & Future prospect of northern expansion of *Aedes albopictus* in Japan

Mutsuo Kobayahi[1], Osamu Komagata[2], Naoko Nihei[3]

[1]National Institute of Infectious Diseases, Japan, [2]National Institute of Infectious Diseases, Japan, [3]National Institute of Infectious Diseases, Japan

Asian tiger mosquito, Aedes albopictus, is one of vectors of the dengue and Chikungunya viruses and is a common mosquito in Southeast Asian and Far Eastern countries including Japan. During past three decades the distribution areas of Ae. albopictus clearly expand to worldwide by world trading of used tiers. In Japan Aedes albopictus distributed widely in Honshu Island with its northern limits between 38° to 40° degrees north. The factors affecting distribution of the species in Japan were studied using the GIS and showed an annual mean temperature higher than 11 Co is most related to the northern limit. During 1998?2010, larval surveillance was carried out in more than 30 cities and towns including rural areas in Tohoku district, the northern limit clearly moved to northward. The future expansion of the distribution of Ae. albopictus was analyzed using 1-km mesh climate data prospected by MIROC (K1) model in 2035 and 2100. From these analyses, the distribution of the mosquitoes clearly expands in the lowland areas of most northern Honshu district in 2035. Ae. albopictus will also invade to Hokkaido Island crossing the Tsugaru Strait until 2100. Our theory was reconfirmed by the technical report published by ECDC in 2009 entitled "Development of Aedes albopictus risk map" .

Aerial vector control following natural disasters in the Southern United States

Mark Breidenbaugh
U.S. Air Force, U.S.A.

Some studies have linked an increasing number of hurricanes to climate change. In the Southern United States, a series of Category 4 & 5 hurricanes since 2005 have caused in their wake significant property damage, loss of life, and generated high numbers of mosquitoes. National and state level public health responses typically involve various vector control measures including the application of insecticides by aircraft over large areas. This paper discusses the type, scope, and results of aerial sprays to control mosquitoes and filth flies following Hurricanes with an emphasis on the U.S. Air Force's methods.

Geographical distribution of larval trombiculid mites in Korea (2005~2007)

Jong Yul Roh[1], Bong Gu Song[2], Won Il Park[3], Eun Hee Shin[4], Chan Park[5], Mi-Yeoun Park[6]

[1]KCDC, Republic of Korea, [2]KCDC, Republic of Korea, [3]KCDC, Republic of Korea, [4]KCDC, Republic of Korea, [5]KCDC, Republic of Korea, [6]KCDC, Republic of Korea

A surveillance of larval trombiculid mites was conducted to clarify the geographical distribution of scrub typhus vectors in Korea by collecting wild small mammals twice a year (spring and autumn seasons) at 24 localities from 2005 to 2007. Among 783 trapped rodents, Apodemus agrarius accounted for 87.4% and the trapping rate at riverside was recorded the highest. A total of 67,325 mites representing 4 genera and 14 species were collected and their chigger index (C. I., No. of chigger mites per one rodent) was 86.0. The predominant species were Leptotrombidium pallidum (52.6%), L. scutellare (27.1%), L. palpale (8.2%), L. orientale (5.6%), and Neotrombicula tamiyai (1.7%). However, the portions of L. scutellare in southern areas including endemic provinces such as Jeollabuk-Do (34.3%), Jeollanam-Do (49.0%), and Gyeongsangnam-Do (88%) were relatively higher than middle areas where L. pallidum was predominant in. Additionally, in autumn season, the density of L. scutellare was increased up to 42.0% while that of L. pallidum was decrease to 37.6%. Now we are performing second periodic surveillance (2011~2013) and trying to develop an alternative method using molecular markers for identification of chigger mites instead of morphological classification.

Prefabricated trap: Application to monitor fly populations in global change Kom Sukontason*, Ratchadawan Ngoen-klan, Kittikhun Moophayak, Tunwadee Klong-klaew, Kabkaew L. Sukontason Department of Parasitology, Faculty of Medicine, Chiang Mai University, Thailand Inevitably, the effect of global warming will trigger the physiological and/or behavioral responses of terrestrial organisms, thereby increasing their populations, including those of some insects in particular areas. The increment of insect populations, especially in those of medical importance, may affect humans by means of involvement with more vectors of disease pathogens. To understand population changes in medically important flies, population monitoring in the natural environment should be performed regularly by using a sweeping or trapping technique. Although several fly trap models have been constructed and utilized, some of them are impractical for fly survey strategy, for example, traps that are too large and heavy for easily transferring collected specimens to the laboratory for investigation. Therefore, we hereby introduce a lightweight and inexpensive apparatus for assembling a fly trap, consisting of 3 parts: 1) frame, made from polyvinylchloride pipe (1.25 cm in diameter), 2) net for fly collection, and 3) entrance dome. Tests of this novel trap, using fresh and tainted pork viscera as bait in field experiments, clearly indicated the great practicality of this device, both for assembling to form a trap and transporting to and from the laboratory. The flies collected revealed 10 species in the family Calliphoridae, 6 species in the family Muscidae, and 3 unidentified species in the family Sarcophagidae.

Seasonal and annual occurrence of blow flies (Diptera: Calliphoridae) associated with longan orchards and a paddy field in Southern Chiang Mai, Thailand

Ratchadawan Ngoen-klan[1], Kittikhun Moophayak[2], Tunwadee Klong-klaew[3], Kim N. Irvine[4], Kabkaew L. Sukontason[5], Kom Sukontason[6]

[1]Kasetsart University, Thailand, [2]Chiang Mai University, Thailand, [3]Chiang Mai University, Thailand, [4]State University of New York, U.S.A., [5]Chiang Mai University, Thailand, [6]Chiang Mai University, Thailand

This blow fly survey was conducted during 2009 and 2010 using traps baited with 1-day tainted viscera in two longan orchards and one paddy field in Hang Dong district, southern Chiang Mai, northern Thailand. Seven species from Calliphorinae and Chrysomyinae subfamilies were identified. In two longan orchards, Chrysomya megacephala was the most common species collected (68.86%), followed by Achoetandrus rufifacies (24.08%), Hemipyrellia ligurriens (6.00%), Hemipyrellia pulchra (0.63%), Lucilia cuprina (0.24%), Ceylonomyia nigripes (0.10%), and Lucilia papuensis (0.10%). In contrast, three species; C. megacephala (89.42%), A. rufifacies (5.74%) and H. ligurriens (4.84%), were collected in a paddy field. Considering the three most common species collected - C. megacephala, A. rufifacies and H. ligurriens - the overall adult population of C. megacephala captured in the two longan orchards and paddy field fluctuated throughout the year with no significant differences between seasons. As for A. rufifacies, collection at a longan orchard (site HD2) amounted to significantly low population during the cool season. Temperature was the only factor displaying weak positive correlation with seasonal occurrence of this species. In the paddy field, there was no seasonal pattern for A. rufifacies collected or climatic factors correlating to the number of flies captured. Regarding H. ligurriens, collection in a longan orchard (site HD1) showed a significantly higher population in the rainy season. High relative humidity and low light intensity are the main factors for increasing the number of H. ligurriens captured as the lowest population in the paddy field was observed clearly during the dry season.

The Great East Japan Earthquake brought unprecedented damages caused by great Tsunami which was unexpected by even experts of disaster. In the field of medical entomology, uncountable number of flies emerged from putrid shes, brown rice and organic fertilizer which were spread from destroyed storehouses on the shoreline. A number of mosquito larvae were observed at newly appeared standing water bodies, a lot of destroyed septic chambers and tanks related to sewage disposal system at tsunami-stricken areas. The members of Department of Medical Entomology, National Institute of Infectious Diseases and Japan Pest Control Association visited Miyagi and Iwate Prefectures of Tohoku Tsunami-stricken regions in 2011 to survey the medically important pest insects. In this symposium, we report, with pictures and movies, the situation of these nuisance and vector insects which explosively emerged at Tohoku eastern seashores.

Life traits of *Aedes mosquitoes* as factors of arboviruses emergence

Didier Fontenille[1], Sebastien Boyer[2], Helene Delatte[3], Jean-Sebastien Dehecq[4]

[1]IRD Montpellier, MIVEGEC, France, [2]IRD, France, [3]CIRAD, France, [4]ARS Reunion, France

Life traits of Aedes mosquitoes as factors of arboviruses emergence Among the >3500 mosquito species described in the world, only a few hundred are able to transmit arbovirus to human. For example, as less than 10 among 920 Aedes species effectively transmit dengue and Chikungunya viruses naturally. Based on recent field and experimental results particularly on Aedes albopictus, we will show the role and relative contribution of the different parameters of vector competence and vector capacity in shaping Aedes-arbovirus interactions and the resulting pathogen transmission dynamics and risk of emergence. These include mosquito life history traits and biology parameters such as population dynamics, longevity, trophic behavior, habitat preference, diapause, genetics, immunity and biotic interactions. The mechanisms and processes underlying the patterns observed in the field should be studied all the way, from molecules to individuals and populations, towards a better understanding of what makes a mosquito vector and how best to control it.

The mosquito *Aedes albopictus* and its vectorial status

Anubis Vega-Rua[1], Marie Vazeille[2], Laurence Mousson[3], Camilo Arias-Goeta[4], Karima Zouache[5], Anna-Bella Failloux[6]
[1]Institut Pasteur, France, [2]Institut Pasteur, France, [3]Institut Pasteur, France, [4]Institut Pasteur, France, [5]Institut Pasteur, France, [6]Institut Pasteur, France

The mosquito Aedes albopictus (Skuse) (Diptera: Culicidae), native to Southeast Asia, has extended its geographical distribution, invading new temperate and tropical regions. Its geographic expansion facilitated by increasing trading and touristic activities led to emergence of arboviruses in unexpected regions such as Southern Europe. The species was recorded for the first time in Albania in 1979, then in Italy where it has become the main pest in urban settings. It is now present in all European countries around the Mediterranean Sea. Ae. albopictus was incriminated as a main vector in the first European outbreak of chikungunya in the province of Ravenna (Italy) in 2007 and responsible of autochthonous cases of chikungunya and dengue in the south of France in 2010. Using experimental infections, we found that populations from South of France were as efficient as Aedes aegypti, the main vector, to transmit both dengue and chikungunya viruses. The large numbers of travellers returning from dengue- and chikungunya-endemic regions may introduce frequently the virus which has been proved to be efficiently transmitted by autochthonous mosquito species. Outbreaks due to both arboviruses should be expected in developed countries where Ae. albopictus is established.

The mosquito immune response modulates vector competence for arthropod-borne viruses

Carol D. Blair
Colorado State University, U.S.A.

RNA interference (RNAi) mediates normal growth and development and limits viral infection and transposon activity in eukaryotic cells. RNAi involves 21 to 30 nucleotide RNAs classified as microRNAs (miRNAs), exogenous and endogenous small interfering RNAs (exo- and endo-siRNAs) and Piwi-interacting RNAs (piRNAs). We have shown that the exo-siRNA pathway is the major mosquito innate immune response and is an important modulator of dengue virus type 2 (DENV2) infection of Aedes aegypti, the major DENV vector. Virus-specific siRNAs (viRNAs) produced by Dicer-2 (Dcr2) cleavage of long dsRNA forms of DENV2 RNA are required to initiate the antiviral exo-siRNA response. The size and polarity of viRNAs from DENV-infected A. aegypti mosquitoes and cultured cells indicate that they are products of Dcr2 cleavage of long dsRNA, whereas cultured A. albopictus C6/36 cells generate DENV2-specific small RNAs with characteristics suggesting they originate from the piRNA pathway. We speculate that a single-nucleotide deletion in C6/36 cell dcr-2 and defective expression or function of Dcr2 might explain the robust growth of arboviruses in the C6/36 cell line compared to growth in Aag2 cells. While this result emphasizes the importance of the exo-siRNA pathway in the mosquito immune response, it also suggests that other small RNA pathways serve back-up or ancillary roles in mosquito antiviral defense. We showed that genetic diversity in A. aegypti miRNA as well as siRNA pathway genes correlates with the rate of DENV dissemination from infected midguts (the midgut escape barrier), suggesting involvement of all the RNAi pathways in mosquito vector competence.

Wolbachia density-dependent inhibition to dengue Virus in three *Aedes* mosquito species

Zhiyong Xi[1], Xiaoling Pan[2], Guoli Zhou[3], Jiahong Wu[4], Guowu Bian[5], Peng Lu[6], Alexander S. Raikhel[7]

[1]Michigan State University, U.S.A., [2]Michigan State University, U.S.A., [3]Michigan State University, U.S.A., [4]Michigan State University, U.S.A., [5]Michigan State University, U.S.A., [6]Michigan State University, U.S.A., [7]Michigan State University, U.S.A.

Wolbachia is a maternal transmitted endosymbiotic bacterium that is estimated to infect up to 65% of insect species. The ability of Wolbachia to both induce viral interference and spread into mosquito vector population makes it possible to develop Wolbachia as a biological control agent for dengue control. While Wolbachia induces resistance to dengue virus in the transinfectedAedesaegypti mosquitoes, a similar effect was not observed in Aedesalbopictus and Ae. polynesiensis, which naturally carryWolbachia infection but still service as dengue vectors. In order to understand the mechanism of this lack of Wolbachia-mediated viral interference, we used both Ae. albopictus cell line (Aa23) and mosquitoes to characterize the impact of Wolbachia on dengue infection. We show that there is a strong negative linear correlation betweenthe genome copy of Wolbachia and dengue virus with a dengue infection completely removed when Wolbacha density reaches a certain level. We then compared Wolbachia density between transinfectedAe. aegyptiand naturally infected Ae. albopictus, and between the wild typeAe. polynesiensis and its transinfected line. All the results support a high Wolbachia density in mosquito somatic tissues will lead to a low mosquito vector competence for dengue virus. We discuss our results in relation todevelopment of novel methods to block disease transmission by mosquitoes carrying native Wolbachia infections.

Progress in understanding RNA interference (RNAi) as a key control mechanism of arbovirus replication and spread in mosquitoes.

Alain Kohl
MRC-University of Glasgow, United Kingdom

Replication and spread of arboviruses is not passively tolerated in mosquitoes, but controlled by host responses. A key mosquito innate immune response limiting arbovirus replication is RNAi. During insect antiviral RNAi responses, virus-induced double-stranded RNA (dsRNA; mainly derived from replication intermediates) is cleaved by the nuclease Dcr-2 into double-stranded siRNAs, also called virus-induced small interfering RNAs or viRNAs in the context of viral infection. These viRNAs are integrated into the RNA-induced silencing complex (RISC), which contains Ago-2 as a key effector protein. Ago-2 will retain one strand of the viRNA to bind complementary viral RNA, which is then cleaved. These processes are still poorly understood in mosquitoes and mosquito cells. I will discuss progress that has been made in understanding induction and effector mechanisms that underlie antiviral RNAi responses mainly against a prototype mosquito-borne alphavirus, Semliki Forest virus (SFV). The genetic flexibility of SFV and SFV-derived viral replicons have proven to be particularly useful to further understand antiviral RNAi. These studies have been carried out in mosquito cell lines which retain functional RNAi responses, which allows tight control of infections. The respective roles of key proteins involved in RNAi and viRNA functions will be highlighted.

Introduction to symbiotic microorganisms associated with medical, hygienic and veterinary pest arthropods

Takema Fukatsu
National Institute of Advanced Industrial Science and Technology (AIST), Japan

Many of notorious pest insects and other arthropods of medical, hygienic and veterinary importance are associated with a variety of symbiotic microorganisms of either obligate or facultative nature. Bacteriocyte-associated, nutrition-provisioning, and obligate bacterial endosymbionts, such as Wigglesworthia and Riesia are known from tsetse flies, lice, bedbugs, etc. Facultative bacterial endosymbionts such as Wolbachia, Rickettsia, Arsenophonus, Sodalis, etc. are found from almost all pest arthropods including mosquitoes, fleas, lice, tsetse flies, ticks, etc. Most of vector-borne human and animal pathogens are regarded as facultative endosymbionts of the vector arthropods. Some facultative endosymbionts like Wolbachia are investigated as promising controlling agents to suppress vector competence of the pest arthropods. Here I present an overview of these relevant issues to prime the symposium. [Supported by BRAIN]

Symbiosis in ticks, and the microbial community associated with South-American tick vector of rickettsiosis

Bessem Chouaia[1], Mariana G. Spolidorio[2], Mario Colucci[3], Sara Epis[4], Daniele Daffonchio[5], Marcelo B. Labruna[6]

[1]University of Milan, Italy, [2]University of Sao Paulo, Brazil, [3]University of Milan, Italy, [4]University of Milan, Italy, [5]University of Milan, Italy, [6]University of Sao Paulo, Brazil

Ticks are ectoparasites, living on the blood of vertebrates. These arthropods are major vectors of a number of diseases, including rickettsiosis, Lyme disease, tularemia, babesiosis. Symbiosis with microorganisms is important in arthropod vectors: symbionts are known to influence the fitness of the arthropods, their capacity to transmit diseases and their resistance to parasites. Symbiotic microorganisms could be exploited to impair the transmission of vector-borne pathogens (symbiotic control). Only a few studies have so far been published on the symbiotic microbiota associated with ticks. Examples of tick-associated symbionts are the intra-mitochondrial bacterium Midichloria mitochondrii and the pathogen-interfering symbiont Rickettsia peacockii. Amblyomma aureolatum and Amlyomma cajennense are South-American ticks, that vector the spotted fever agent Rickettsia rickettsii. They share the same ecological niche. But, while A. aureolatum shows high susceptibility to R. rickettsii, with high infection rates, A. cajennense displays low susceptibility, with lower prevalence. In order to understand the mechanisms behind the difference in susceptibility between the two species, we investigated their associated microbiota and its reaction to the infection with R. rickettsii. DGGE and 16 rRNA library analysis were carried out on lab colonies of A. aureolatum and A. cajennense, before and after infection with the pathogen. The microbiota of the two species displayed overlapping patterns, but the change in the symbiont structure after the infection was more pronounced in the case of A. aureolatum. For both species, the dominant bacterium was a Francisella-like bacterium, that belongs to an emerging clade of tick-associated symbionts.

Midichloria, the bacterium that invades tick mitochondria

Claudio Bandi[1], Iacopo Gnappo Leardini[2], Bessem Chouaia[3]
[1]University of Milano, Italy, [2]University of Milano, Italy, [3]University of Milano, Italy

Midichloria mitochondrii is the only intra-mitochondrial bacterium thus far described. This microorganism resides in the cytoplasm and mitochondria of the hard tick Ixodes ricinus, infecting the oocytes and other cells of the female reproductive tissues. In addition to I. ricinus, other ticks have been shown to harbor close relatives of Midichloria. The presence of Midichloria in the reproductive apparatus of female ticks ensures its transmission to the progeny. The location in the mitochondrion is peculiar, in that Midichloria occupies the intermembrane space. This location might suggest different kinds of interactions with the host cell. Relatives of Midichloria are assumed to act as energy-scavenging parasites; some of these have also been shown to possess the complete gene set for the synthesis of heme. We have recently published the genome of M. mitochondrii, whose annotation confirms the presence of the genetic apparatuses for the synthesis of both ATP/ADP translocase and heme. Ticks are assumed to be unable to synthesize this prosthetic group. A function for Midichloria might thus be hypothesized, i.e. the provisioning of heme to the host (as in the case of the interaction between Wolbachia and filarial nematodes). Genome annotation also revealed the presence of genes coding for a complete flagellar apparatus and for the cbb3 cytochrome oxidase (previously unreported in Rickettsiales). Phylogenomics showed that these genes have been vertically inherited from the common ancestor of Rickettsiales and mitochondria. These findings suggest a novel scenario on the origin of the eukaryotic cell.

Lariskella arthropodarum, a novel facultative endosymbiont clade in the Rickettsiales associated with stinkbugs, fleas and ticks

Yu Matsuura[1], Yoshitomo Kikuchi[2], Xian-Ying Meng[3], Ryuichi Koga[4], Takema Fukatsu[5]
[1]University of Tsukuba, Japan, [2]AIST, Japan, [3]AIST, Japan, [4]AIST, Japan, [5]AIST, Japan

The alphaproteobacterial order Rickettsiales contains well-known bacterial groups such as Wolbachia, Rickettsia, Ehrlichia and Anaplasma, whose members are associated with a diverse set of host/vector species with various relationships ranging from parasitic/pathogenic through commensalistic to mutualistic. Stinkbugs of the genus Nysius possess a pair of red-pigmented bacteriomes in the abdomen, wherein the obligate endosymbiont Schneideria nysicola is harbored (Matsuura et al. 2012a). In addition, we also identified an array of facultative endosymbionts, Wolbachia, Rickettsia and a novel alphaproteobacterium, designated as Lariskella arthropodarum. Of 343 insects representing 24 populations and 4 Nysius species, 285 insects (83.1%) were associated with Lariskella. Further survey of diverse stinkbugs representing 24 families, 191 species, and 582 individuals detected Lariskella from additional 12 species representing 6 families. Molecular phylogenetic analysis showed that Lariskella-allied endosymbionts are found not only from stinkbugs but also from fleas and ticks, forming a coherent monophyletic group in the Rickettsiales. In situ hybridization and electron microscopy identified small filamentous Lariskella cells in various tissues of Nysius plebeius including the bacteriome and ovary (Matsuura et al. 2012b). The Rickettsiales is known for a number of animal and human pathogens including Rickettsia prowazekii for epidemic typhus, R. rickettsii for Rocky Mountain spotted fever, Ehrlichia chaffeensis for monocytic ehrlichiosis, etc. Notably, Mediannikov et al. (2004) detected a 16S rRNA gene sequence of Lariskella from blood and biopsy samples of acute fever patients bitten by Ixodes ticks. Hence, potential medical relevance of Lariskella should be a focal issue in future studies. [Supported by BRAIN]

Cardinium of *Ixodes scapularis*: Its Characteristics and Genome Sequence

Hiroaki Noda[1], Yuki Nakamura[2], Akiya Jouraku[3], Kimiko Yamamoto[4], Timothy J Kuritti[5]

[1]National Institute of Agrobiological Sciences, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]National Institute of Agrobiological Sciences, Japan, [4]National Institute of Agrobiological Sciences, Japan, [5]University of Minnesota, U.S.A.

Cardinium, a facultative symbiont of arthropods and nematodes, has attracted attention as a manipulator of host sex and reproduction since 2001 (Weeks et al.; Zchori-Fein et al.). Cardinium is a member of the Bacteroidetes group and is in a different lineage from Wolbachia, which belongs to alphaproteobacteria and also cause reproductive abnormality in host arthropods. Cardinium of Ixodes scapularis (IsCar) was cultured by chance in a tick cell line in 1996 and identified as being structurally similar to other symbiotic microorganisms found in arthropods. The phenotypes that IsCar may induce in host ticks are not known. We have maintained the IsCar in the silkworm cell line aff3 and examined gene expression of IsCar?infected host cells using a silkworm microarray. A Wolbachia (wStr) from the small brown planthopper Laodelphax straitellus was also cultivated in aff3 cells and we compared gene expression in cells infected with IsCar or wStr. Wolbachia did not up-regulate host insect immune genes whereas Cardinium clearly up-regulated them. Whole genome sequences of arthropod symbionts have been accumulated during these 10 years. Determination of genome sequence of IsCar contributes to the study of host-symbiont interaction, especially manipulation mechanisms of endosymbionts. We prepared genomic DNA from isolated IsCar from the silkworm cell line. Sequences were determined by Sanger sequencing using 2 Kb and 5 Kb shotgun libraries and by pyrosequencing and short-read sequencing. Genome sequence assembly was hindered by the presence of many transposon sequences in the IsCar genome, resulting in 121 sequence scaffolds. [Supported by BRAIN]

Mosquito symbionts as a tool for mosquito borne disease control

Guido Favia
University of Camerino, Italy

Mosquitoes have a relevant ability to adapt to very different types of habitats, thus they are present all around the world. It is highly likely that the microbiota of the mosquitoes had a key role in establishing their great capacity to adapt to different environments. A deep knowledge of the mosquito?microbiota relationships may give the chance to better understand some traits of mosquito biology and may help the development of innovative mosquito-borne disease-control strategies aimed to reduce mosquito vectorial capacity, with particular regards to those inhibiting pathogen development within mosquito transmission. In this context, since some years my research group at the University of Camerino has started a study for the identification of mosquito symbionts. On the basis of their particular features we have mostly focused our interest on two of them: 1) The acetic acid bacterium Asaia 2) The yeast Wickeramomyces anomalus -Asaia is a Gram-negative α-proteobacterium, found in some mosquito species including several malaria vectors and dengue virus vectors. Asaia is the most prevalent bacteria in both natural and lab mosquito populations and its prevalence often reaches 100%. Asaia has been detected in in the midgut, salivary glands, and reproductive organs of the mosquito. For all these reasons Asaia could has been proposed to express anti-pathogen(s) molecules directly in the midgut of the mosquito to exert an inhibitory effect against pathogens.

The mosquito gut microbiota in the war against human pathogens

George Dimopoulos
Johns Hopkins University, U.S.A.

The resident microbiota of insect vectors can impede transmission of human pathogens. Recent studies have highlighted the capacity of endogenous bacteria to decrease viral and parasitic infections in mosquito and tsetse fly vectors by activating their immune responses or directly inhibiting pathogen development. These microbes may prove effective agents for manipulating the vector competence for malaria and other important human pathogens, as well as representing promising sources of anti-pathogen therapeutic natural products. We have identified a variety of microbes of the mosquito midgut microflora with potent in vivo and in vitro activities against the dengue virus and different stages of the malaria parasite Plasmodium. The potential of these microbes for disease control will be discussed.

Wolbachia genes acquired through lateral gene transfer contribute to feeding habit of the host bedbug

Naruo Nikoh[1], Takahiro Hosokawa[2], Kenshiro Oshima[3], Masahira Hattori[4], Takema Fukatsu[5]

[1]The Open University of Japan, Japan, [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan, [3]University of Tokyo, Japan, [4]University of Tokyo, Japan, [5]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Diverse insects utilize their specific diets. If not all, many of such food adaptations are attributable to their nutrition-provisioning bacterial symbionts. These symbionts are often harbored in specialized cells called bacteriocytes that constitute a symbiotic organ bacteriome. Facultative and parasitic bacterial symbionts like Wolbachia have been regarded as evolutionarily distinct from such obligate nutritional mutualists like Buchnera in aphids. However, we recently discovered that, in the bedbug Cimex lectularius, a Wolbachia endosymbiont resides in a pair of bacteriomes as an obligate nutritional mutualist. The symbiont is vertically transmitted via ovarial passage, elimination of the symbiont resulted in retarded growth and sterility of the host, and these deficiencies were rescued by oral supplementation of B vitamins that are lacking in blood meal of the host. Here we report the complete genome sequence of the mutualistic Wolbachia strain wCle associated with C. lectularius. Gene repertoire and evolutionary patterns in the wCle genome were similar to those of other Wolbachia genomes. Intriguingly, the wCle genome encoded a set of genes for biosynthesis of B vitamins, which are lacking in other Wolbachia genomes. Molecular phylogenetic analysis showed that the vitamin synthesis genes are closely related to those of phylogenetically unrelated bacteria, indicating lateral transfer origin of those genes. In addition, elimination of the specific B vitamin from the artificial diet resulted in retarded growth of aposymbiotic insects. These results strongly suggest that horizontal gene acquisition by the Wolbachia strain might contribute to the blood feeding habit of the host bedbug. [Supported by BRAIN]

Characterisation of imidacloprid resistance in the housefly *Musca domestica* (Diptera: Muscidae)

Jing Li[1], Qingmin Wang[2], Pei Liang[3], Xiwu Gao[4]

[1]China Agricultural University, China, [2]China Agricultural University, China, [3]China Agricultural University, [4]China Agricultural University, China

A housefly population collected from filed (IFS) was selected continuously with imidacloprid to establish the resistant strain (IRS) and near isogenic lines of resistance (N-IRS) and susceptibility (N-ISS) to imidacloprid were built up. The N-IRS possessed about 200 times of imidacloprid resistance compared to the homologous susceptible strain. The level of cross resistance to beta-cypermethrin dramatically decreased from 1175-fold in the IRS to 18-fold in the N-IRS. The N-IRS lost the cross resistance to azamethiphos though the original cross resistance to this insecticide only is 4 times. However, no difference of cross resistance to acetamiprid was observed between the IRS and N-IRS because of the same action mechanism with imidacloprid. Three synergists (piperonyl butoxide, S,S,S-tributylphosphorotrithioate and diethyl maleate) all showed the significant synergism to imidacloprid in N-IRS, indicating that the multiple factors involved in N-IRS resistance to imidacloprid. De novo analysis of transcriptome on both N-ISS and N-IRS of Musca domestica was carried out. The expression levels of 99 of cytochrome P450 genes exhibited upregulation, 111 of cytochrome P450 genes down regulation in the N-IRS. 8 genes showed upregulation and 12 genes down redulation for glutathione S-transferase. 11 genes showed upregulation and 11 genes down redulation for carboxylesterase. 2 genes showed upregulation and 1 genes down redulation for acetylcholinesterase. 17 genes showed upregulation and 31 genes down redulation for nicotinic acetylcholine receptor in the N-IRS. These results are very useful for clarifying the imidacloprid resistance in Musca domestica.

Sustaining malaria control by tackling pyrethroid resistance in *Anopheles mosquitoes*.

Rodolphe William Poupardin[1], Christopher M. Jones[2], Sara N. Mitchell[3], Craig S. Wilding[4], Hilary Ranson[5]

[1]Liverpool School of Tropical Medicine, United Kingdom, [2]Liverpool School of Tropical Medicine, United Kingdom, [3]Liverpool School of Tropical Medicine, United Kingdom, [4]Liverpool School of Tropical Medicine, United Kingdom, [5]Liverpool School of Tropical Medicine, United Kingdom

The World Health Organization estimates that there were 216 million malaria cases resulting in 655,000 deaths in 2010. With increasing reports of drug resistance and no vaccine, controlling the mosquito vector is the best method of malaria prevention. This typically involves the use of pyrethroid insecticides, either via insecticide treated bednets or indoor residual spraying. However, the efficiency of these tools is been threatened by the emergence of resistance to insecticides in malaria vectors. Understanding the underlying mechanisms is fundamental for the control of resistant mosquito populations. Resistance to pyrethroids has been frequently associated with a series of mutations in the target-site sodium channel, known as kdr mutations (target-site resistance) and also to an increase metabolism of insecticide by detoxification enzymes (metabolic resistance). Two main mutations occurring at codon 1014 and resulting in the substitution of leucine to serine (kdr East) or phenylalanine (kdr West) are now routinely screened to detect any signs of insecticide resistance in Anopheles populations. Recently, our group discovered a new kdr mutation N1575Y that gives, in association with the L1014F mutation an increase resistance of mosquitoes to DDT and permethrin. In parallel, recent microarray studies on pyrethroid resistant Anopheles strains detected several potential candidate genes, mainly detoxification genes potentially involved in pyrethroid resistance. One of them, CYP6M2, coding for a cytochome P450 monooxygenase has beeen shown to metabolize pyrethroids and DDT. The role of the different kdr mutations and the metabolic resistance on the control of pyrethroid resistant Anopheles will be discussed.

Spread of overexpressing CYP9M10 (cytochrome P450) haplotypes in southern house mosquito and its possible implication for vector control

Kentaro Itokawa[1], Osamu Komagata[2], Shinji Kasai[3], Hitoshi Kawada Kawada[4], Takashi Tomita[5]

[1]National Institute of Infectious Diseases, Japan, [2]National Institute of Infectious Diseases, Japan, [3]National Institute of Infectious Diseases, Japan, [4]Nagasaki University, Japan, [5]National Institute of Infectious Diseases, Japan

Overexpressions of a cytochrome P450 gene, CYP9M10, have been shown to associate with pyrethroid resistance in several independent strains of the southern house mosquito Culex quinquefasciatus. There are two forms of overproducing CYP9M10 haplotypes sharing an insertion of the same transposable element, while one is duplicated (D-Cu(+) form) and the other is not duplicated (Cu(+) form). The D-Cu(+) form was apparently derived from a haplotype of the Cu(+) form through a recent gene duplication after the TE insertion. The D-Cu(+) haplotype showed higher overexpression and was associated with stronger resistance compared to the Cu(+) haplotype, suggesting that the D-Cu(+) haplotype has acquired stronger efficacy to resistance by gene duplication and/or other cis-acting regulatory mutation(s). CYP9M10 haplotypes with the Cu(+) and D-Cu(+) forms have been found from strain or samples originating from geographically distinct areas including Asia, Middle East and Africa suggesting worldwide distribution of these haplotypes. On the other hand, the nucleotide sequence among the Cu(+) and D-Cu(+) haplotypes were highly identical regardless of place they were isolated indicating that they share a very recent common ancestral haplotype. Although the Cu(+) and D-Cu(+) CYP9M10 haplotypes are considered to spread under insecticide selection, they are not considered as an immediate threat to the actual control practices so far because the resistances associated with these haplotypes have been confirmed larval specific while pyrethroids are mainly used to combat adult mosquitoes. However, some attention may be required to see whether there is another regulatory variant of CYP9M10 overexpressed even in adult stage.

Proliferation of pyrethroid-resistant bed bugs in Japan

Osamu Komagata[1], Shinji Kasai[2], Kentaro Itokawa[3], Takashi Tomita[4]

[1]National Institute of Infectious Diseases, Japan, [2]National Institute of Infectious Diseases, Japan, [3]National Institute of Infectious Diseases, Japan, [4]National Institute of Infectious Diseases, Japan

The bed bugs are reemerging pest in Japan. The infestations of bed bug are increasing from the second half of the 2000s. The one important factor seems pyrethroid resistance. The bed bugs highly resistant to pyrethroids were already found in U.S. and elsewhere. It was probable that same situation in the pyrethroid resistance as U.S. in Japan. Recent studies have shown that amino acid mutations in sodium channel (VSSC) associated with pyrethroid resistance in bed bug, Cimex lectularius. Sixty seven colonies (total: n=461) of bed bug were collected from various locations in Japan from 2009 to 2011. The frequencies of two mutations (V924L and L925I) in the sodium channel gene were investigated in the bed bug colonies. Among the 67 colonies, only single mutation (L925I) found in the 54 colonies, only double mutation(V924L and L925I) found in the 6 colonies. One colony consisted of individuals with both the single and the double mutation. No mutation was found in the remaining 7 colonies. I925 common in two haplotypes was found at broad area in Japan and the frequency was ca.90%. The almost bed bugs were homozygous for I925. The living bed bugs in collected were assayed for pyrethroid resistance. The bioassays showed that the almost bed bugs were pyrethroid resistant, which had I925 mutation(s). Pyrethroids are less effective in bed bug control in Japan.

Molecular mechanism and detection of pyrethroid resistance in the common bed bug, *Cimex lectularius*

Deok Ho Kwon[1], Keon Mook Seong[2], Kyeong Sup Yoon[3], John Marshall Clark[4], Si Hyeock Lee[5]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]University of Massachusetts, Republic of Korea, [4]University of Massachusetts, U.S.A., [5]Seoul National University, Republic of Korea

The common bed bug, Cimex lectularius L. (Hemiptera: Cimicidae), is an ectoparasitic pest that feeds on humans as well as other mammals. We investigate that point mutations on the voltage-sensitive sodium channel are associated with the resistance to pyrethroids. Two point mutations (V419L and L925I) in the voltage-sensitive sodium channel (VSSC) α-subunit gene have been identified in deltamethrin-resistant bed bugs. L925I, located the intracellular loop between IIS4 and IIS5, has been previously found in a highly pyrethroid-resistant populations of whitefly. V419L, located in the IS6 transmembrane segment, is a novel mutation. To establish a population-based genotyping method as a molecular resistance monitoring tool, a quantitative sequencing (QS) protocol was developed. Frequency prediction equations were generated from the plots by linear regression, and the signal ratios were shown to highly correlate with resistance allele frequencies ($r2 > 0.993$). In addition to QS, the filter contact vial bioassay (FCVB) method was established and used to determine the baseline susceptibility and resistance of bed bugs to pyrethroids. A pyrethroid-resistant strain showed > 9375- and 6990-fold resistance to deltamethrin and ?-cyhalothrin, respectively. Resistance allele frequencies in different bed bug populations predicted by QS correlated well with the FCVB results, confirming the roles of the two mutations in pyrethroid resistance. Taken together, employment of QS in conjunction with FCVB method should greatly facilitate the detection and monitoring of pyrethroid resistant bed bugs in the field.

Transcriptional analysis of development and detoxification in *Culex pipiens quinquefasciatus*

Liangzhen Yan[1], Pengcheng Yang[2], Feng Jiang[3], Enbo Ma[4], Chuanling Qiao[5], Le Kang[6], Feng Cui[7]

[1]Chinese Academy of Sciences, China, [2]Chinese Academy of Sciences, China, [3]Chinese Academy of Sciences, China, [4]Shanxi University, China, [5]Chinese Academy of Sciences, China, [6]Chinese Academy of Sciences, China, [7]Chinese Academy of Sciences, China

The genomes of three major mosquito vectors of human diseases have been previously sequenced. However, unlike Anopheles gambiae and Aedes aegypti, which have large amounts of gene expression data, Culex pipiens quinquefasciatus has limited transcriptomic resources. In the present study, cytochrome P450 monooxygenases, glutathione S-transferases, and carboxylcholinesterases of C. p. quinquefasciatu were analyzed for phylogenetic classification. Compared with three other dipteran species, gene expansion in Culex mainly occurred in the genes of α-esterases, juvenile hormone esterases, and P450 CYP325s. Gene expression during various developmental stages and the differential expression responsible for parathion resistance were profiled using the digital gene expression (DGE) technique. A total of 13314 genes were expressed in five DGE libraries. Genes with signal transduction and odorant binding functions were prominently expressed during egg development. Genes involved in proteolysis, glycosphingolipid biosynthesis, and purine metabolism were preferentially expressed at the larval stage. One fourth of the carboxylcholinesterase and P450 genes were expressed at unique stages. Fifteen detoxification genes were expressed at higher levels in a parathion-resistant strain than in a susceptible strain. The results of the present study provide new insights into the functions and evolution of three detoxification gene families and comprehensive transcriptomic resources for C. p. quinquefasciatus.

Management of head louse resistance using molecular tools

Si Hyeock Lee
Seoul National University, Republic of Korea

Head lice resistance to permethrin is mainly conferred by the knockdown resistance (kdr), a voltage-sensitive sodium channel (VSSC) insensitivity factor. Three VSSC mutations (M815I, T917I and L920F) have been identified. Functional analysis of the mutations using the house fly VSSC expressed in Xenopus oocytes revealed that the permethrin sensitivity is reduced by the M827I (M815I) and L932F (L920F) mutations when expressed alone but virtually abolished by the T929I (T917I) mutation, either alone or in combination. Thus, the T917I mutation is primarily responsible for permethrin resistance in head lice. Comparison of the expression rates of channel variants indicates that the M815I mutation may play a role in rescuing the decreased expression of channels containing T917I. A step-wise resistance monitoring system has been established based on molecular resistance detection techniques. Quantitative sequencing (QS) has been developed to predict the VSSC mutation frequency at a population basis. The speed, simplicity and accuracy of QS made it an ideal candidate for a routine primary resistance monitoring tool to screen a large number of wild populations as an alternative to conventional bioassay. As a secondary monitoring method, real-time PASA (rtPASA) has been devised for more precise determination of low resistance allele frequencies. To obtain more detailed information on resistance allele zygosity, as well as allele frequency, serial invasive signal amplification reaction (SISAR) has been developed as an individual genotyping method. Our approach of using three tiers of molecular resistance detection should facilitate large-scale routine resistance monitoring of permethrin resistance in head lice using field-collected samples.

Molecular evidence of *Bartonella quintana* in *Pediculus humanus capitis* (Pediculidae: Anoplura) infesting young people in selected villages in Laguna province, Philippines

Arlene Garcia Bertuso[1], Mutsuo Kobayashi[2], Kyoko Sawabe[3]

[1]University of the Philippines Manila, Philippines, [2]National Institute of Infectious Diseases, Japan, [3]National Institute of Infectious Diseases, Japan

Bartonella quintana is a bacterium that multiplies in the gut of the body louse (Pediculus humanus humanus) causing trench fever in humans. B. quintana has been found in body lice of homeless, alcoholic and immunocompromised persons from cities in Europe, USA and Japan. Sasaki and associates (2002) found that body lice from 16.7% (2/12) homeless persons were positive for B. quintana by PCR. They showed that head lice (P.h. capitis) may be involved in the transmission of B. quintana in Nepal. Pediculosis by head lice is a major public health problem among children in the Philippines. This study determined the incidence of B. quintana in head lice collected from young people in selected villages in the province of Laguna, Philippines. Head lice were collected using fine-toothed comb, pooled by host (e.g. 1-10 head lice/pool) and stored at -80ºC. Fifty pools were homogenized and processed for DNA extraction using the protocols of Mini Kit (QIAGEN, USA) and the Blood and Body Fluid Spin. Gene purification and DNA sequencing were also conducted. PCR based detection using Bartonella genus specific primers demonstrated the presence of B. quintana in 2% (1/50) head lice pools. This is the first molecular evidence of the incidence of B. quintana in head lice in the Philippines. Further investigation is needed to determine the prevalence of B. quintana in head lice in the country. The information is useful for the national government to plan and implement interventions, health ordinances and advocacy on pediculosis and Bartonella infections in the Philippines.

Diversity of *Bartonella* spp. in flea vectors - insights from studies in Israel

Shimon Harrus[1], Danny Morick[2], Irina Khokhlova[3], Yuval Gottlieb[4], Boris Krasnov[5]

[1]Hebrew University of Jerusalem, Israel, [2]Hebrew University of Jerusalem, Israel, [3]Ben Gurion University, Israel, [4]Hebrew University of Jerusalem, Israel, [5]Ben Gurion UNiversity, Israel

Bartonellae are small gram-negative bacteria belonging to the alpha-2 subdivision of the Proteobacteria. They infect mammalian erythrocytes and endothelial cells and are transmitted by blood-feeding arthropods. Rodents were found to have a high prevalence of Bartonella infection worldwide, with high diversity of Bartonella spp. and strains. The close contact between human and rodent populations creates permissive conditions for transmission of Bartonella spp. from rodents to humans. A recent survey carried out in the Tel Aviv region, the biggest urban center in Israel, demonstrated the occurrence of a single Bartonella strain closely related to B. elizabethae and B. tribocorum in commensal rats (Rattus rattus). Another study carried out in the Negev desert demonstrated sixteen different Bartonella genotypes in flea pools collected from 5 different wild rodents (jirds, gerbils and mice), indicating the great diversity of Bartonella spp. in rodent fleas, and their capacity to harbor several Bartonella genotypes. Bartonella henselae was detected in three flea-pools indicating the public health importance of rodent-related Bartonella. A recent experimental study have shown that the rodent flea, Xenopsylla ramesis, can acquire several Bartonella genotypes from different wild rodents, and can remain persistently infected for prolonged periods, suggesting their potential capability to serve as competent vectors for Bartonella strains. Additional experimental study showed that X. ramesis is a competent vector of Bartonella OE 1-1. The observed differences in Bartonella prevalence and diversity among rodents in urban versus rural regions request further investigation. The finding of zoonotic Bartonella spp. in rodent fleas has public health importance.

Bartonella species in rodent fleas in Japan

Hidenori Kabeya[1], Soichi Maruyama[2]
[1]Nihon University, Japan, [2]Nihon University, Japan

Accumulating studies have shown that Bartonella species are widely prevalent among wild rodents at high rate. Effective transmission of the organisms is thought to be indispensable to maintain the high prevalence of Bartonella in natural environments. The purpose of this study is to assess the roles of flea infestation for the transmission of the organisms among wild rodent in Japan. Blood and flea (32 Ctenophthalmus congener truncus, 5 Neopsylla sasai, and 3 Hystrichopsylla microti) samples were collected from wild rodents (31 Apodemus speciosus, 5 A. argenteus, and 17 Myodes rufocanus bedfordiae), which were captured in Hokkaido, Japan and examined for Bartonella infection. Bartonellae was isolated from 36 of 53 (67.9%) animals and the DNA was detected from 16 of 40 (40.0%) flea samples. Sequence analysis demonstrated that 4 of 16 (25%) of Bartonella -positive animals were infested with the flea from which the closely related Bartonella DNA was detected, indicating the possibility that fleas acquired Bartonella from the infested rodents. It was indicated that host-parasite specificity may have been established between Apodemus mice and B. grahamii and that the transmission may be accomplished by fleas, N. sasai and/or C. congener truncus by comparing the DNA of Bartonella found in each rodent and its fleas. The efficacy of Bartonella transmission may differ depending on the combination of rodent and flea species. Efficient transmission by favorable vectors in wild rodents and optimal host-parasite interactions could contribute to the high prevalence and long-term infection of Bartonella species.

Ecology of malaria vectors and their *Plasmodium* parasites in Malaysia

Indra Vythilingam
University of Malaya, Malaysia

The four species of Plasmodium affecting humans and their vectors have been well established. However, in Southeast Asia the fifth malaria parasite, P. knowlesi is affecting humans in areas where long-tailed macaques and suitable Anopheles vectors co-exist. With deforestation and changing ecological landscape, simian malaria vectors are also feeding on humans thus transmitting the parasites to them. Two established vectors, Anopheles latens and Anopheles cracens are simio-anthropophagic and acrodendrophilic, thus are excellent vectors of simian malaria. These mosquitoes belong to the An. leucosphyrus group which has limited distribution in Southeast Asia. Studies are currently ongoing to determine the other vectors which keep the transmission on going in the non-human primates. Since the country has embarked on a malaria elimination programme, it is important to know the vectors that have colonized new areas due to changing ecological landscape.

Surveillance of malaria vectors and *Plasmodium vivax* in Korea

Terry Allen Klein[1], Heung-Chul Kim[2], Won-Ja Lee[3], Hee-Choon Sam Lee[4], Dong-Kyu Lee[5], Tae-Song Chong[6]

[1]Public Health Command Region-Pacific, U.S.A., [2]65th Medical Brigade, Republic of Korea, [3]Korea National Institute of Health, Republic of Korea, [4]65th Medical Brigade, U.S.A., [5]Kosin University, Korea, Republic of, [6]65th Medical Brigade, Republic of Korea

Plasmodium vivax was endemic on the Korean Peninsulae for many centuries until the late 1970's. Malaria re-emerged among ROK military populations along the demilitarized zone (DMZ) in 1993 and rapidly spread to nearby civilian communities. By 2000, the total number of reported cases increased to 4,142. From 2000 through 2004, the number of malaria cases rapidly declined to 826, most likely as a result of increased awareness, vigilance, and an expanded ROK military chemoprophylaxis program that included 160,000 soldiers. While it was presumed that malaria would rapidly expand throughout Korea, nearly all transmission remained near the DMZ. As new information was discovered, including two previously unrecognized species (An. kleini and An. belenrae), geospatial distributions (high populations of An. kleini populations near the DMZ with low populations south of Seoul), and vector potential, the identification of malaria health threat risks became more apparent. With the integration of air-conditioned barracks from ill-kept tents, malaria cases among US military decreased dramatically. In addition to preliminary evidence, which demonstrates that civilian communities serve as reservoirs for vivax malaria and infections among ROK military, high infection rates among mosquitoes were observed in mosquitoes collected in the DMZ. These data indicate that the malaria situation is much worse in North Korea than in South Korea. Comprehensive mosquito-borne disease surveillance programs are required to better understand the dynamics of the epidemiology of malaria in Korea and to identify present and future health risks.

Taxonomic status and distribution of *Anopheles Hyrcanus* Group vectors of malaria in Asia

Leopoldo M. Rueda
Walter Reed Army Institute of Research, U.S.A.

Anopheles Hyrcanus Group includes several species which are vectors of malaria and other mosquito borne diseases in the Oriental and Palearctic Regions. The group comprises 30 known species world-wide, representing about 42% of the species in the Myzorhynchus Series of genus Anopheles Meigen subgenus Anopheles Meigen. Twenty eight of these species are found in the Oriental and Eastern Palearctic Regions and three in the Western Palearctic Region. In Asian countries (e.g. China, Korea and Japan), the known or potential vectors of human malaria include An. sinensis Wiedemann, An. kleini Rueda, An. pullus Yamada, An. belenrae Rueda and An. lesteri Baisas and Hu. The Hyrcanus Group-species breed in various habitats, such as rice paddies, irrigation ditches, drainage ditches, ground pools, swamps, stream margins, inlets and pools, uncultivated fields, and artificial containers. Surveys from various Asian countries showed that An. sinensis is the most dominant species from rice paddies, irrigation ditches and other habitats. The taxonomic status, distribution records, and medical importance of several Asian species are noted and discussed.

VectorMap, an online mapping resource for malaria vectors and related groups in Asia and Africa

Desmond H. Foley[1], Richard C. Wilkerson[2], Jason H. Richardson[3], Lewis S. Long[4], Leopoldo M. Rueda[5]
[1]WRAIR, U.S.A., [2]WRAIR, U.S.A., [3]WRAIR, U.S.A., [4]WRAIR, U.S.A., [5]WRAIR, U.S.A.

VectorMap (www.vectormap.org) is a free resource for mapping collection data and distribution models of arthropods (mosquitoes, ticks, sand flies) involved in disease transmission. VectorMap is an outgrowth of MosquitoMap that currently hosts around 250,000 mosquito records, and over 45 ecological niche distribution models for Asian and African anopheline mosquito species. Collection data are comprised of vouchered specimen information, and both unpublished and unpublished observation data, and are quality controlled for geographic and taxonomic information. Users can view the locations of past malaria vector collections, the results of models that predict the geographic extent of individual vector species, and various malaria distribution layers, all in a GIS-type setting. Collection records are searchable and downloadable, and collection forms, and Excel mapping tools, are available for data contributors to compile and map their data. Two enhancements to VectorMap are under development ? the Mal-area Calculator (MAC) and VectorSurv. The MAC allows the quantification, for any area of interest, of the overlap of vectors, hosts, and disease, to generate an estimate of hazard and risk. The Mal-area approach emphasizes the independent contribution to disease risk of the vector species predicted present. VectorSurv is designed for surveillance data and allows the user to understand when vector population densities are above average, by providing information-rich graphs of species seasonality and abundance. These resources are offered to the international malaria vector control community as a focal point for publishing vector collection data, and for exploring the nexus between geography and malaria transmission.

Influence of pyriproxyfen on the emergence and survival of malaria vectors in Thailand

Alongkot Ponlawat
Armed Forces Research Institute of Medical Sciences, Thailand

In the current study, we evaluated the efficacy of pyriproxyfen on the emergence and survival of two important malaria vectors (Anopheles minimus [laboratory strain] and An. epiroticus [field strain]) under the laboratory and semi-field conditions. Anopheles minimus has been incriminated as a vector of malaria in Thailand. It is commonly found throughout the country along shaded areas with slow running streams; in forests associated with cleared foothills that are the margin of villages. Anopheles epiroticus is considered to be the malaria vector in coastal areas in Thailand. It breeds mainly in man-made brackish water containers (eg. old fish fermented cement tanks, tanks for shrimp culture). The residual effect of pyriproxyfen for Anopheles control was evaluated for 12 weeks. Moreover, the pyriproxyfen horizontal transfer from the pyriproxyfen-treated surface to the breeding containers by An. minimus and An. epiroticus was conducted in large mosquito cages.

Molecular identification and population structure of the malaria vector, *Anopheles sinensis* (Diptera: Culicidae) in China

Yajun Ma[1], Jiannong Xu[2], Yong Fan[3], Manni Yang[4], Jing Wu[5], Ying Ma[6]

[1]Second Military Medical University, China, [2]New Mexico State University, U.S.A., [3]Second Military Medical University, China, [4]Second Military Medical University, China, [5]Second Military Medical University, China, [6]Second Military Medical University, China

Anopheles sinensis is a competent malaria vector in China. It is difficult to distinguish by morphology because of some sibling species. And there is no adequate data of A. sinensis population genetics available yet. The AS-PCR assay for distinguishing A. sinensis from Hyrcanus group was established. The species-specific primers were designed by rDNA-ITS2 sequences differences. The length polymorphism of PCR products can identify the A. sinensis, A. pullus and A. lesteri. Five microsatellite loci were used to estimate population genetic diversity, genetic differentiation and demographic history of A. sinensis from 14 representative localities in China. All 5 loci were highly polymorphic across populations, with high allelic richness and heterozygosity. Hardy-Weinberg disequilibrium was found in 12 populations associated with heterozygote deficits, which was likely caused by the presence of null allele and the Wahlund effect. Bayesian clustering analysis revealed two gene pools, grouping samples into two population clusters; one includes six and the other includes eight populations. Out of 14 samples, six samples were mixed with individuals from both gene pools, indicating the coexistence of two genetic units in the areas sampled. The overall differentiation between two genetic pools was moderate (FST=0.156). No evidence of isolation by distance was detected among populations neither within nor between the two clusters. Variable effective population size and other demographic effects of historical population perturbations could be the factors affecting the population differentiation. The structured populations may limit the migration of genes under pressures/selections, such as insecticides and immune genes against malaria.

Malaria vector control in western Kenya

Noboru Minakawa[1], Hitoshi Kawada[2], Gabriel O Dida[3]
[1]Nagasaki Univiersity, Japan, [2]Nagasaki Univiersity, Japan, [3]Kenya Medical Research Institute, Kenya

Insecticide treated bed nets (ITNs) have been used to control malaria vectors in Kenya. However, malaria transmission remains high among residents in the Lake Victoria region. It is reasonable to assume that the environment associated with the lake still maintains a high number of malaria vectors. To reveal the factors affecting the high transmission, we monitored use and coverage of bed nets, vector abundance, malaria prevalence among children and related environmental factors for five years. Then, we examined their relationships and evaluated the effectiveness of ITNs. We found that rainfall and lake water level were important factors affecting vector abundance and transmission. The recent intensified climate variation was partially responsible for the patterns and amount of rainfall and lake fluctuation. Although ITNs were effective, the use and coverage of ITNs started decreasing within two years after the mass distribution. The ITN use was particularly low among school children and their prevalence was high. We found the limitation of ITNs, and additional vector control measures are necessary for a considerable reduction of malaria transmission in the region.

Geographical distribution of *Anopheles gambiae* and *An. arabiensis* in Kenya.

Kyoko Futami[1], Gabriel Dida[2], Noboru Minakawa[3]
[1]*Nagasaki University, Japan,* [2]*Kenya Medical Research Institute, Kenya,* [3]*Nagasaki University, Japan*

Since major African malaria vectors, Anopheles gambiae and An. arabiensis have different vectorial capacities, understanding their geographical distributions and relative abundance is important for malaria control. Although the distributions of these species in Kenya had been reported, the available information was old and leaned on a few specific areas. We collected the An. gambiae complex larvae from about 500 sites in Kenya from 2008 to 2010. Our research revealed that 1) An. arabiensis distributed throughout Kenya while An. gambiae distributed mainly in the western part, 2) An. arabiensis also occurred in high altitude areas including Nairobi where malaria vectors had not been recorded for decades, and 3) the relative abundance of An. arabiensis remained high even in low malaria transmission areas. Further we predicted the suitable habitat range of each species using maximum entropy niche modeling with environmental covariates of each collection sites. Environmental covariates included a) mean monthly minimum and maximum temperatures, b) mean monthly precipitation, c) elevation and d) land cover type. The best model was selected based on AUC. The selected model revealed that dry season precipitation is the most important factor of presence of each species. This study added several new distributional records of malaria mosquitoes in Kenya and new information on the environmental factors affecting mosquito distribution.

Multimodal pyrethroid resistance in malaria vectors in western Kenya

Hitoshi Kawada
Nagasaki University, Japan

In Kenya, a large number of ITNs have been distributed through programs of MOH and NGOs, resulting in a significant reduction in malaria deaths. Since then, however, a high level of pyrethroid resistance caused by the high frequency of point mutations (L1014S) have been detected in An. gambiae s.s. and P450-related pyrethroid resistance seemed to be widespread in both An. arabiensis and An. funestus s.s. A lack of cross-resistance between DDT and permethrin was also found in An. arabiensis and An. funestus s.s., while An. gambiae s.s. was resistant to both insecticides. It is noteworthy that that 2 different resistance mechanisms have developed in the 2 sibling species in the same area individually. The cross resistance between permethrin and DDT in An. gambiae s.s. may be attributed to the high frequency of kdr mutation, which might be selected by the frequent exposure to ITNs. Similarly, the metabolic pyrethroid resistance in An. arabiensis and An. funestus s.s. is thought to develop without strong selection by DDT. The allelic frequency of L1014S was higher in An. gambiae s.s. and An. arabiensis in western regions, although the allelic frequency in An. arabiensis was quite lower than in An. gambiae s.s. The present contribution of the L1014S mutation to pyrethroid resistance in An. arabiensis may be negligible. However, the homozygous frequency could increase with continuing selection pressure due to expanded LLIN coverage in the future. The possible use and mode of action of LLIN against the above pyrethroid-resistant malaria vectors will also be discussed.

Molecular identification of *Anopheles gambiae* complex species (Diptera: Culicidae) and its molecular forms in Liberia

Nermeen Talaat Fahmy[1], Peter Joseph Obenauer[2]
[1]*U.S Naval Medical Research unit no. 3, Egypt,* [2]*U.S Naval Medical Research unit no. 3, Egypt*

The Anopheles gambiae complex includes a group of 5 morphologically indistinguishable species which represent the main malaria vector in Sub-Saharan Africa. We collected mosquitoes throughout 3 counties in Liberia from May, July, September and November 2011 using 5 trapping techniques. Molecular techniques were used to identify the Anopheles complex using the differences of rDNA region (28S coding region and 5` end of IGS region) between species and the molecular forms (S and M) of An. gambiae s.s specimens. Over 1500 An. gambiae specimens were collected and identified. For each specimen, legs were excised,DNA extracted and a multiplex PCR was performed using specific primers for each species. After PCR, RFLP (Restriction Fragment Length Polymorphism) method was performed using HahI restriction enzyme. This enzyme digests specific restriction site located at rDNA region of An. gambiae S form gave 2 fragments, due to the absence of this restriction site in M form it remains as a one single fragment. Preliminary results show the widespread of the An. gambiae s.s in Liberia collection sites; only one An. melas/An.merus was detected. We found 77% of An.gambiae specimens were S form while 22% were M form. Only 1% of specimens was determined to be hybrid M/S.

Ecological and evolutionary determinants of host species choice in African malaria vectors

Issa Lyimo
Ifakara Health Institute, Tanzania

Here we conducted for the first time an experimental investigation of the strength of selection acting on African malaria vectors An. arabiensis and An. gambiae s.s to preferentially specialize on human instead of animal hosts within natural transmission settings. We used novel semi-field mosquito biosphere within a malaria endemic region of Africa to directly investigate the strength of counterselection placed on vector host species choice by the control measures commonly used in the field: bednets. We experimentally measured the feeding success and subsequent fitness of the two major African vectors (> 16,000 mosquitoes) on humans and other potential host types they co-occur. Experimental data were used to parameterize a stochastic life ? history model that combined all measured impacts of host species choice on vector fitness to predict the cumulative effects on the key metric of selection: total lifetime reproductive success. We demonstrated that mosquito fitness depends on host species choice, and the use of bednets substantially reduced the fitness ranking of humans relative to other animal alternatives. For An. arabiensis, the vector now dominating in many parts of Africa, the use of bednet widened the fitness differential between humans and cows to an extent where strong selection for zoophily is expected when most people use nets, and cattle are available. This provides baseline evidence that evolutionary sustainable control approaches incorporating the use of selection for mosquitoes to shift their host choice could enhance the effectiveness of frontline disease control strategies

Assessment of perceptions of community users and bioefficacy of permethrin incorporated OlysetTM net (LLIN) distributed 5 years before in India

P K Mittal[1], Ripu Daman Sood[2], Neera Kapoor[3], R K Razdan[4], V K Dua[5], A P Dash[6]

[1]National Institute of Malaria Research, India, [2]Indira Gandhi National Open University, India, [3]Indira Gandhi National Open University, India, [4]National Institute of Malaria Research, India, [5]National Institute of Malaria Research, India, [6]WHO, South East Asia Regional Office, India

In Indian context it is important to evaluate long-term field performance of long lasting insecticidal nets (LLIN), especially the reduction in malarial cases and assessment of community acceptance. Hence we carried out community based survey in a District GautamBudh Nagar, U.P, where Olyset nets were distributed 5 years ago, to assess the efficacy of Olyset nets on malarial cases and safety related to it. Three villages were selected for trial and baseline entomological and epidemiological data was collected for one year. After one-year OlysetTM nets were distributed in one village, untreated nets were distributed in another village and third village was kept as control where nets were not distributed. A survey of OlysetTM nets was conducted to examine the perception of community members regarding durability, wash resistance, and comfort of use. Bioefficacy of field used nets was determined by bioassays against malaria vectors and comparing the malariometric indices before distribution and during 5th year of Olyset nets use. Use of OlysetTM nets reduced the malarial cases drastically. Bioefficacy studies proved that Olyset nets fulfill the criteria of LLIN. People liked the size, colour of these nets and appreciated nets in relation to the efficacy against mosquitoes and preferred their larger mesh size as it permits more airflow. OlysetTM nets fulfill the LLIN criteria and show durability with much longer insecticide persistence even after 5 years of use. Even epidemiological data have confirmed that these nets are highly effective and proved to be a good physical barrier between man? vector contacts.

Can olfactory memory alter oviposition choice in malaria vectors?

Manuela Herrera-Varela[1], Jenny Lindh[2], Steve Lindsay[3], Ulrike Fillinger[4]

[1]London School of Hygiene and Tropical Medicine, Kenya, [2]Royal Institute of Technology, Sweden, [3]London School of Hygiene and Tropical Medicine, United Kingdom, [4]London School of Hygiene and Tropical Medicine, Kenya

Oviposition site selection in mosquitoes is mediated by physical and chemical factors present in the aquatic habitats. Various organic materials and bacteria have been associated with this process. Though mosquitoes are innately attracted to or repelled by certain compounds, the chemical character of potential oviposition sites change over space and time. Mosquitoes might respond to this variability by altering their behaviour based on prior experience as a larva. Olfactory memory and its impact on oviposition choice has been described for Aedes and Culex species but has not yet been explored in anophelines. If the oviposition behaviour is inherited and defined in Anopheles mosquitoes, this means that the chemicals involved in this process can be identified, manipulated and used in 'attract & kill' or 'push-pull' strategies to improve malaria vector control. To investigate olfactory memory in oviposition by Anopheles gambiae, larvae were reared in grass infusion previously avoided by gravid adults in open field habitats. The resulting adults were offered grass infusion and tap water in two-choice cage bioassays. Preferences were compared to mosquitoes reared in tap water. Mosquitoes that were conditioned in grass infusion and those reared in tap water preferred to lay eggs in tap water. The repellent effect of the grass infusion cannot be altered by rearing the vector in it. In contrast to some Culex and Aedes species the ability of An. gambiae to select oviposition sites appears not to be affected by the experience of inmature stages.

A novel approach of evaluating and analyzing oviposition bioassays for malaria mosquitoes

Michael Nyanganga Okal[1], Jenny Lindh[2], Steve Lindsay[3], Ulrike Fillinger[4]

[1]London School of Hygiene and Tropical Medicine, Kenya, [2]Royal Institute of Technology - KTH, Sweden, [3]London School of Hygiene and Tropical Medicine, United Kingdom, [4]London School of Hygiene and Tropical Medicine, Kenya

As physiological resistance to insecticides and behavioural avoidance of interventions continue to defy costly frontline mosquito management strategies in Africa, the need to develop and integrate sustainable and effective solutions for dealing with these errant vectors of malaria remains pressing. A good understanding of the process of host seeking in Anopheles gambiae s.l. has instigated many effective intervention strategies. In much the same way, new insight on the little defined return journey when gravid mosquitoes leave their resting places after successful blood meals and lay eggs in select aquatic breeding sites could inform new fronts in management of these vectors. We looked into the periodicity of oviposition together with egg number and distribution as well as the impact of different host blood meal sources with the object of developing sound systems for studying the process and cues of oviposition site selection in Anopheles gambiae s.l. The choice of host is demonstrated to influence the proportions of caged An. gambiae s.s. that become gravid following blood meals in favour their natural host, humans. Individual mosquitoes showed a wide variability in numbers of eggs laid and spread these across more than one substrate making it difficult to quantify its preferences for oviposition. Caged gravid mosquitoes consistently laid eggs in early scotophase with over 90% laying eggs between 17:00 and 21:00hrs. We present a novel way of implementing and analysing data from oviposition bioassays for An. gambiae s.l.

Biological and behavioral characterization of *Anopheles funestus*-like species from Northern Malawi

Vezenegho Samuel Bumuh[1], Richard Hunt[2], Maureen Coetzee[3], Lizette Koekemoer[4]

[1]University of Witwatersrand, South Africa, [2]University of Witwatersrand, South Africa, [3]University of Witwatersrand, South Africa, [4]University of Witwatersrand, South Africa

Introduction Malaria in Malawi is transmitted by An. gambiae, An. arabiensis and An. funestus. This vector diversity is further complicated by the recently discovered new An. funestus-like species which is morphologically similar to An. funestus, and found in association with humans. This study investigated the biology and behavior of the An. funestus-like species in relation to malaria transmission. Materials and Methods Mosquitoes were collected resting indoors and outdoors from study sites. Specimens were identified morphologically and by PCR as An. funestus-like species. An. funestus-like were analyzed for blood meal source and Plasmodium sporozoite infection using ELISA. Results In total, 392 adult An. funestus group mosquitoes were collected during April and September, 2010. Karonga contributed for 63.8% and Likoma Island 36.2%. Of these, An. funestus-like comprised 8.7% (34/392). Most of the An. funestus-like species were collected resting indoors 91.2% (31/34) compared to outdoors 8.8% (3/34). The species was predominant in the dry season 64.7% (22/34). Nineteen An. funestus-like females were analyzed for blood meal source. Goat blood was found in 10 specimens, of which 7 had also taken cow blood. An overall dry season infection rate of An. funestus-like species by Plasmodium vivax was 5% (1/20) in this study and 3.1% (2/64) from a 2009 analysis. However, false-positivity still needs to be excluded. Discussion and conclusion This study confirmed An. funestus-like species occurring in sympatry with An. funestus group members. An. funestus-like species was predominantly found resting indoors but preferring animal over human blood. Its vectorial capacity needs confirmation

Invasive species, conservation biology, and biological control - a three way collision: Now time to join forces

Roy Van Driesche[1], Mark Hoddle[2], Charlotte Causton[3]
[1]University of Massachusetts, U.S.A., [2]University of California Riverside, U.S.A., [3]Charles Darwin Foundation, Ecuador

Invasive species may strongly affect native plants and in doing so, affect biodiversity at both the plant level and at the level of the specialized insects that depend on the plants. Biological control may be used to suppress densities of such invasive pests and often represent the only practical, permanent and widespread solution to such problems. Here we examine importance of invasive species as threats to native insect biodiversity, relative to other categories of threats and the potential of biological control to contribute to the restoration of native species or ecosystems damaged by invasive organisms. We focus on two invasive insects, Icerya purchasi Maskell (Hemiptera: Monophlebidae) in the Galapagos Islands and Agrilus planipennis Fairmaire (Coleoptera: Buprestidae) in the ash forests of the north central United States. The application of biological control is not embraced fully by the conservation biology and ecological restoration community, in part for lack of familiarity, and in part because of the perception that introduced natural enemies may themselves become damaging to native biodiversity. We argue that ecosystem restoration following invasions by highly damaging species requires use of biological control within a conservation biology framework with the active joint efforts of both biological control scientists and conservation biologists. Efforts to promote this approach will be discussed.

Ecological impacts of red imported fire ant *Solenopsis invicta* Buren (Hymenoptera: Formicidae) on ant community in China

Biqiu Wu[1], Guangwen Liang[2], Yijuan Xu[3], Ling Zeng[4], Yongyue Lu[5]

[1]South China Agricultural University, China, [2]South China Agricultural University, China, [3]South China Agricultural University, China, [4]South China Agricultural University, China, [5]South China Agricultural University, China

Red imported fire ant (RIFA) Solenopsis invicta Buren is hazardous alien species, which had been found in Guangdong, China on Sept., 28, 2004. The impact of the fire ant invasion on ecosystem was thought to be significant, and cause the decrease of the biodiversity in the previous reports. RIFA also often competed with native ants and replaced them finally. As a new invasive species in south China, effect of the fire ant on the biodiversity, especially the ants community with the similar niche needs to be known further. Therefore, the effects of RIFA invasion on the diversity of ant community in the orchard, wasteland and lawn in Guangdong were studied by the method of the bait trap and pitfall trap in this study. The competition between RIFA and native ants was also observed.

Impacts of two alien ants, *Anoplolepis gracilipes* and *Pheidole megacephala*, on native ant fauna in Okinawa, Japan

Nozomi Kadowaki[1], Hitoshi Ohnishi[2], Hirotaka Tanaka[3], Kazuki Tsuji[4], Naoto Kamata[5]

[1]University of Tokyo, Japan, [2]University of the Ryukyus, Japan, [3]University of the Ryukyus, Japan, [4]University of the Ryukyus, Japan, [5]University of Tokyo, Japan

Exclusion of native species is one of the most serious impacts caused by invasive alien species. Anoplolepis gracilipes (yellow crazy ant: YCA) and Pheidole megacephala (bigheaded ant: BHA) are widely known as invasive ant species due to their negative impacts on ecosystems in the world. However, even though they have been reported as alien species in Okinawa main land, their impacts on native ant fauna are unknown. Ant fauna was investigated at sites infested by YCA or BHA and non-infested sites. Abundance of each of all ant species and species richness were compared between them. For both of the two alien species, ant fauna differed significantly between infested and non-infested sites (ANOSIM, $p<0.01$). However, the effects differed greatly between the two species. YCA did not have negative impacts on abundances of native species nor species richness. Tetramorium kraepelini and Monomorium chinense increased in the infested sites (GLMM, $p<0.05$). In contrast, BHA had strong negative impacts on native ant fauna. Abundances of three major species, Tetramorium bicarinatum, Monomorium chinense, and Pheidole fervens, and species richness decreased in the infested sites (GLMM, $p<0.05$). However, in our survey, BHA disappeared from five sites out of seven, in which BHA was distributed in the preliminary survey. This result indicates that BHA colony does not persist for long though the reasons remain unclear. Thus, in Okinawa, the impacts of invasion by YCA and BHA on native ant fauna are relatively small in comparison to previous studies conducted in abroad.

Understanding invasion history and the eradication project of the Argentine ant in Japan

Maki N. Inoue[1], Koichi Goka[2]
[1]*National Institute for Environmental Studies, Japan,* [2]*National Institute for Environmental Studies, Japan*

The Argentine ant, Linepithema humile, has successfully spread from its native range in South America across much of the globe. A form of social structure, supercoloniality, whereby individuals from separate nests cooperate, is attributed to its successful worldwide expansion. The Argentine ant, first noted in 1993, is now found in several regions of Japan. Therefore, early detection as well as rapid control is required to prevent further expansion of the species. We attempted to demonstrate the genetic structure of introduced Argentine ant populations in Japan and how they relate to other introduced and native populations to understand its invasion history. Furthermore, we have demonstrated the eradication project of Argentine ant in Tokyo to provide successful example for the support the ongoing battle against Argentine ant.

Ecological and economic impact of the alien B and Q whiteflies of the *Bemisia tabaci* species complex in China

ShuSheng Liu
Zhejiang University, China

The whitefly Bemisia tabaci (Gennadius) (Hemiptera: Aleyrodidae) is a species complex containing over 30 morphologically indistinguishable species. In the last 20-30 years, two of the putative species, commonly known as the B and Q whiteflies, have invaded many parts of the world. In China, the alien B and Q whiteflies as well as 13 indigenous species have been recorded. Records indicate that the first invasion in China by B occurred around 1994 and that by Q occurred around 2003, and both were probably aided by imports of ornamental plants. By 2003, B had been recorded from 15 provinces, mostly along the south-east costal regions, and by 2009/2010, B had been recorded from 27 provinces and Q from 26 provinces, nearly all over China. Following the invasions, whitefly outbreaks occurred on many field and vegetable crops, and indigenous whitefly species were displaced by the invaders in many regions of invasion. Meanwhile, disease pandemics caused by indigenous begomoviruses, which are exclusively transmitted by whiteflies, started to occur in southeast China around 2000. Following the invasion of the alien Tomato yellow leaf curl virus in 2005-2006, disease pandemics caused by TYLCV and indigenous begomoviruses have been increasing rapidly and widespread, causing enormous yield losses in a number of crops particularly tomato. With their widespread distribution and further invasions into more remote areas, the invasive whiteflies and the begomoviruses they transmit present one of the biggest challenges China agricultural production has to face in the years to come.

The impact of the introduced parasitoid *Torymus sinensis*, a biological control agent of *Dryocosmus kuriphilus*, on the indigenous parasitoid *T. beneficus* on chestnut trees in Japan

Kaori Yara
National Agricultural Research Center, Japan

Hybridization between the introduced parasitoid Torymus sinensis and the indigenous congener T. beneficus had attracted attention since T. sinensis was first introduced to control the invasive pest Dryocosmus kuriphilus in Japanese chestnut orchards; researchers were concerned that the hybridization might interfere with the biological pest control by the introduced parasitoid. Such apprehension disappeared as the damage caused by D. kuriphilus decreased drastically. However, morphologically intermediate individuals between the two Torymus species had appeared in the field after the release of T. sinensis. Thus, there has been renewal of interest in the hybridization, e.g. the non-target effect of biological control, in recent years. I have used molecular markers for hybridization surveys in the field, not only because T. sinensis and T. beneficus are similar morphologically, but also because there are two emergence types (early- and late-spring strains) in T. beneficus that cannot be easily discriminated except for the molecular markers. Our surveys show that 1) T. sinensis displaced the two strains of T. beneficus in Japanese chestnut orchards, 2) the hybridization between T. sinensis and early-spring T. beneficus occurred at low frequency (≤ 1%) and that 3), on the other hand, the hybrid F1s between T. sinensis and late-spring T. beneficus were detected at higher frequency (≤ 20%). These results indicate that hybridization played more important role in the displacement of late-spring T. beneficus by T. sinensis than that of early-spring T. beneficus.

The invasive bark beetle, *Ips grandicollis*, and climate change: dual risks to bio-control of the woodwasp *Sirex noctilio*

Fazila Yousuf[1], Geoff M Gurr[2], Catherine W Gitau[3], Angus J. Carnegie[4], Robin A. Bedding[5], Richard Bashford[6]
[1]Charles Sturt University, Australia, [2]Charles Sturt University, Australia, [3]Charles Sturt University, Australia, [4]Forest Science Centre, Australia, [5]CSIRO Entomology, Australia, [6]Forestry Tasmania, Australia

The woodwasp Sirex noctilio is an exotic pest that can cause extensive losses to pine plantations by introducing its symbiotic fungus Amylostereum areolatum along with a phytotoxic mucus during oviposition. In recent decades a successful bio-control program has operated in Australia using the nematode Beddingia (=Deladenus) siricidicola which feeds upon A. areolatum in pine trees and parasitises S. noctilio causing sterility. Efficiency of this bio-control program is thought to be affected by another exotic pest, the bark beetle Ips grandicollis and its associated symbionts. Ips grandicollis attacks the "trap trees" used to inoculate bio-control nematodes into the S. noctilio population. This may reduce the attractiveness of trap trees to S. noctilio and interfere with B. siricidicola thereby compromising successful bio-control. This paper will report on a major project in which field and laboratory studies have investigated the severity of this problem, interactions between the fungi and nematodes associated with the insects, and possible management strategies. Collectively, the results suggest that climate change and I. grandicollis constitute significant risks to the success of the bio-control program for S. noctilio in Australia.

Decline of native ladybird beetles caused by an invasive alien predator

Oldrich Nedved[1], Helen E Roy[2], Tim Adriaens[3], Nick J.B. Isaac[4], Marc Kenis[5], Thierry Onkelinx[6], Gilles San Martin[7], Peter M.J. Brown[8], Louis Hautier[9], Remy Poland[10]

[1]University of South Bohemia and Biology Centre AS CR, Czech Republic, [2]Centre for Ecology & Hydrology, United Kingdom, [3]Research Institute for Nature and Forest, Belgium, [4]Centre for Ecology & Hydrology, United Kingdom, [5]CABI Europe, Switzerland, [6]Research Institute for Nature and Forest, Belgium, [7]Universite catholique de Louvain, Belgium, [8]Anglia Ruskin University, United Kingdom, [9]Universite Libre de Bruxelles, Belgium, [10]Clifton College, United Kingdom

We documented the decline of distribution range (Belgium and Britain) and abundance (Belgium, Britain, Switzerland, Czech Republic) of formerly common and widespread native ladybird beetles (Coleoptera: Coccinellidae) before and after the establishment of Harmonia axyridis that is a globally rapidly expanding invasive alien species. The distribution data were collected mainly from public surveys verified by recognised experts. Most species studied showed substantial declines attributable to H. axyridis. The two spot ladybird, Adalia bipunctata, declined by 30% (Belgium) and 44% (Britain) over five years after the arrival of H. axyridis. The trends in the abundance of ladybird beetles are based on data collated through systematic surveys of deciduous trees in the four countries. These trends revealed similar patterns of declines across three countries. In the Czech Republic, where H. axyridis arrived later, the abundance of many species decreased before the arrival of H. axyridis and thus its contribution to their decline was not significant. The invasive alien species H. axyridis was proved to cause decline in native biodiversity by displacing native ladybirds in Europe, mainly those with high niche overlap, probably through predation and competition for prey.

Reproduction and critical pupation weight in the invasive and native populations *Harmonia axyridis* (Coccinellidae, Coleoptera)

Nataliia Beliakova
All-Russian institute of plant protection, Russia

The Harmonia axyridis (Pallas) imagoes, pupae and larvae were collected at the territory of the Far East and Czech Republic in summer-autumn 2010-2011. In 3-4 days after a molting to IV instars the Harmonia larvae were placed individually without food. Lethality of the H. axyridis as a function of the larvae weight had the threshold character and was described by the S-like curve of logistic regression. The critical pupation weight, at which about 50% of individuals survive, in the invasions Czech population is 26.3 mg, in the Far East population 29.0 mg. It is possible to assume that decrease of the critical pupation weight in the invasions populations is one of those adaptive advantages which have allowed H. axyridis to expand its area. The minimum weight of females in the Czech population is 12.5 mg, in Far East - more than 16.0 mg. The reproduction of these small females corresponded to the mean value for the populations. The average size of an eggs batch is 24-27 eggs that a little more than in Far East populations - 19 eggs. We have not found correlations between the size of an eggs batch and ovarioles number, and also in weight of a female H. axyridis.

Habitat disturbance disturbance differentially benefits exotic over native coccinellids in agricultural landscape mosaics

Tania Zaviezo[1], Audrey Grez[2], Tatyana Rand[3], Francisca Castillo[4]
[1]Universidad Catolica de Chile, Chile, [2]Universidad de Chile, Chile, [3]USDA-ARS Northern Plains Agricultural Research Lab, U.S.A., [4]Universidad de Chile, Chile

Both anthropogenic habitat disturbance and the breadth of habitat use by exotic species have been found to facilitate invasion into novel environments, and these factors have been hypothesized to be important within coccinellid communities specifically. This study addressed two questions: 1) Do exotic species benefit more than native species from human disturbed habitats? 2) Are exotic species more generalized in their habitat use than natives within the invaded range or can their abundance patterns be explained by specialization on the most common habitats? We quantified the use of different habitat types by native and exotic coccinellid beetles by sampling individuals in nine landcover types that spanned a gradient in disturbance intensity, and represented the dominant natural, semi-natural and agricultural habitats in the landscape. Our results provide strong support for the hypotheses that more disturbed habitats are differentially invaded. Both the proportion of exotic individuals, and the proportion of exotic species increased significantly (4.8 fold and 1.3 fold respectively) with increasing disturbance intensity. In contrast, we found no evidence that exotic species were more generalized in their habitat use than native species, in fact the trend was in the opposite direction. The abundance of exotic specialized coccinellid species was not correlated with the area of the land cover types in the landscape. The results suggest that successful exotic coccinellids may be "disturbance specialists" that thrive within human modified habitats. Therefore, to avoid the expansion of invasive species in agricultural landscapes, less disturbed agricultural production systems could be promoted.

Invasive Species and Quarantine

The spread of the Asian honeybee, *Apis florea* in Sudan: a test case for invasive insect species

Mogbel Ahmed Abdalla El-Niweiri[1], Robin F A Moritz[2]

[1]*National Centre for Research (NCR) Sudan Academy of Sciences, Sudan,* [2]*Martin-Luther-Universitat Halle-Wittenberg, Germany*

The spread of the dwarf honeybee, Apis florea, in Sudan along the River Nile in a linear fashion provides a good model to study the population dynamics and genetic analyses of a honeybee invasion. We used microsatellite DNA analyses to asses the population structure of both invasive A. florea and native Apis mellifera along the river. The invasive A. florea had significantly higher population densities than the wild native A. mellifera. Nevertheless, we found no indication of competitive displacement, suggesting that although A. florea has a high invasive potential it coexists with native A. mellifera along the river Nile. On the other hand this high population of A. florea in Sudan appeared to be originated from a single colony introduction more than two decades ago.

Biological attributes contributing to the invasiveness of *Sitona lepidus* in New Zealand and the success of its introduced biological control agent *Microctonus aethiopoides*

Philippa Jane Gerard[1], Colin Ferguson[2], Scott Hardwick[3], Mark McNeill[4], Craig Phillips[5]

[1]AgResearch, New Zealand, [2]AgResearch, New Zealand, [3]AgResearch, New Zealand, [4]AgResearch, New Zealand, [5]AgResearch, New Zealand

Sitona lepidus Gyllenhal (Coleoptera: Curculionidae) was first reported in New Zealand in 1996 and rapidly became a major pest of white clover (Lolium perenne L.). Half of New Zealand's land area consists of pasture, and this provided S. lepidus with plentiful resources and few natural enemies or competitors. The combination of good flight capability, physical robustness of the adult to withstand and be transported by agricultural machinery and vehicles, and wide climatic tolerance enabled it to spread the length of the country (1,600 km) by 2010. The pattern of invasion demonstrated both natural and assisted dispersal. The species' invasiveness as been facilitated by its flexible life cycle duration, long lived adult stage, and high reproductive rate. In 2006, an Irish biotype of Microctonus aethiopoides Loan (Hymenoptera: Braconidae) was released for biological control of S. lepidus. It has also established and dispersed very rapidly, and often suppresses S. lepidus populations within 2 ? 3 years of its establishment in a new locality. Attributes contributing to the success of the parasitoid include asexual reproduction, density dependent semi-gregarious clutch size (1-4 offspring per host), multiple generations/ year and dispersal of the parasitoid as eggs or early instar larvae within the adult stage of its host. The founding of new populations from as few as ten parasitoids was an important aspect of the biological control release programme in the North Island where the weevil was already widespread before M. aethiopoides was introduced.

Asymmetric reproductive interference between specialist and generalist predatory *Harmonia* ladybirds

Suzuki Noriyuki[1], Naoya Osawa[2], Takayoshi Nishida[3]
[1]Tohoku University, Japan, [2]Kyoto University, Japan, [3]University of Shiga Prefecture, Japan

Invasive generalist predators often displace similar native species through intraguild predation, resource competition, and escape from predation. By contrast, other negative interspecific interactions, such as reproductive interference, are often neglected in the study of invasive generalist predators. In this study, we examined interspecific sexual interactions in two predatory Harmonia ladybirds in their native range in Japan. Harmonia axyridis is a generalist predator, now colonizing the Americas and Europe, whereas H. yedoensis is a rare specialist predator found in Japan that preys only on pine aphids. We showed that mating success substantially decreased in H. yedoensis but not in H. axyridis when adults of the two species were experimentally housed together. Our results indicate that asymmetric reproductive interference from the dominant species may restrict resource use by the non-dominant species. Based on these findings, we discuss the possibility that reproductive interference from invasive generalist predators may affect abundance and resource use of similar native species during biotic invasions.

Invasive Species and Quarantine

Evaluating gene flow of the western corn rootworm in a European hybrid zone

Gerald Bermond[1], Aurelie Blin[2], Marc Ciosi[3], Thomas Guillemaud[4]

[1]INRA of Sophia Antipolis, France, [2]INRA of Sophia Antipolis, France, [3]INRA of Sophia Antipolis, France, [4]INRA of Sophia Antipolis, France

The western corn rootworm Diabrotica virgifera is one of the most serious pests of maize in North America. It is now an invasive pest in Europe. D. virgifera originates in North America and has been introduced several times in various European locations since the 1990's. Two European invasive outbreaks that were initially geographically disconnected are currently in contact and form a hybrid zone in northern Italy. We used this hybrid zone to estimate D. virgifera dispersal by performing an analysis of microsatellite frequency clines (a cline is a continuous variation of allele frequency in space). In absence of selection and given the date of contact between the outbreaks, the slope of the microsatellite frequency clines provides an estimate of gene flow across the hybrid zone. The linkage disequilibrium between the microsatellite loci provides another estimate of gene flow. The cline slope and linkage disequilibrium were estimated by maximum likelihood and provided gene flow estimate with narrow support limits.

Invasive Species and Quarantine

Population genetics of interactions *Leptinotarsa decemlineata* and *Coccinella septempunctata*

Konstantin Kitaev[1], Maxim Udalov[2], Galina Benkovskaya[3]

[1]Institute of biochemistry and genetics of Ufa Scientific Center of Russian Academy of Sciences, Russia, [2]Institute of biochemistry and genetics of Ufa Scientific Center of Russian Academy of Sciences, Russia, [3]Institute of biochemistry and genetics of Ufa Scientific Center of Russian Academy of Sciences, Russia

Colorado potato beetle (Leptinotarsa decemlineata Say) is invasive species in the Eurasia and the pest of potatoes. He moves slowly through Russia and 35 years ago colonized the Southern Urals. Seven-spot ladybird (Coccinella septempunctata L.) widespread in central Russia, lives in grassy communities, feeds mainly on aphids, and beneficial to agriculture as a biological control agent. Visual observations, the content in the laboratory and the data of PCR - analysis of the gut content of C. septempunctata adults demonstrated they feed on the eggs (possibly small larvae) of the L. decemlineata . Seven-spot ladybirds feeding on the eggs and larvae of Colorado potato beetle differ from ladybirds feeding on the aphids and leads to the development of stress reactions. We conducted a genetic analysis using RAPD - PCR and morphometry to determine the process of adapting population of C. septempunctata to feeding eggs of the L. decemlineata. Analysis of heterozygosity and interpopulation polymorphism C. septempunctata shows the differences between individuals, fed on eggs of Colorado potato beetle and do not fed. Feeding on the invasive species leads to a rapid microevolutionary changes in the population of C. septempunctata. Investigation funded Russian Fund Base Research (grant No 11-04-97022-r_povolzhie_a).

Population genetics of the first plataspid species complex (Hemiptera: Plataspidae) reported in North America

Tracie M. Jenkins[1], Tyler D. Eaton[2]
[1]The University of Georgia, U.S.A., [2]The University of Georgia, U.S.A.

The state of Georgia, USA, was the Northern Hemisphere entry point for a new Asian insect symbiosis. The insect, Megacopta cribraria, was first reported in October 2009 feeding on kudzu and clinging to the sides of houses in North Georgia by the thousands seeking overwintering shelter under eaves and in attics. Since 2009 the Asian insect has established itself as an urban nuisance and a pest of soybeans and other legumes. Populations have spread rapidly from the state of Georgia into at least eight contiguous U.S. states and into Central America with reports of new infestations coming in almost daily. Insect and endosymbiont-specific polymerase chain reaction (PCR) primers were used to generate gene and genomic sequence data from insect collections across the range of infestation. Analyses of these data revealed a lack of insect maternal diversity and two major endosymbionts: a primary gamma-proteobacterium, a known nutritionally beneficial obligate, and a secondary alpha-proteobacterium, reported to manipulate insect reproduction in favor of females, but may be functioning differently in this Megacopta species. A chi square analysis of 2000 randomly collected bugs showed no significant difference between males and females. Gamma- and alpha-proteobacteria may, therefore, be nutritionally beneficial and thereby contributing to the insect's fitness and awesome invasive power. We present the genetic evidence from the perspective of a Megacopta interspecies complex in order to understand the origin, dispersal and adaptive potential of this insect.

Cloning, expression and characterization of mitochondrial manganese superoxide dismutase from the Whitefly, *Bemisia tabaci*

Xianlong Gao
Zhejiang University, China

The mitochondrial manganese superoxide dismutase (mMnSOD) is an important metalloenzyme that catalyzes the dismutation of the superoxide anion into hydrogen peroxide. In this study, an mMnSOD was cloned from the invasive Mediterranean cryptic species of the whitefly Bemisia tabaci complex. Sequence analysis indicated the full length cDNA of mMnSOD is of 1,210 bp with a 675 bp open reading frame, corresponding to 224 amino acids with 25 residues of mitochondrial targeting sequence. The predicted protein has a calculated molecular weight of approximately 24.5 kDa and an estimated pI of 8.97. In comparison with the MnSODs of various vertebrate and invertebrate animals, four conserved amino acids for manganese binding (H54, H102, D186 and H190) and MnSOD signature from 186 to 193 (DVWEHAYY) were observed. Recombinant mMnSOD was expressed in Escherichia coli and the enzymatic activity of purified mMnSOD was assayed under various temperatures. In addition, the in vivo activities of MnSOD in the whitefly were measured under various conditions including exposure to low (4°C) and high (40°C) temperatures, transfer from a favorable (cotton) to an unfavorable host plant (tobacco), and treatment with pesticides. We found that the activity of MnSOD is closely related to various stress conditions. The results indicated that the whitefly mMnSOD is involved in the cellular stress response and anti-oxidative processes.

Aggressive interactions between *Solenopsis geminata* and both social forms of *S. invicta* in Taiwan

Li-Chuan Lai[1], Kuo-Hsun Hua[2], Wen-Jer Wu[3]
[1]Providence University, Taiwan, [2]National Taiwan University, Taiwan, [3]National Taiwan University, Taiwan

Fire ants represent a significant hazard for humans and animals living in endemic areas; they also exhibit agonistic behavior toward non-nestmates. Solenopsis geminata and both social forms of S. invicta were accidentally introduced into Taiwan. In the present study, the differences in aggressive behaviors of three fire ant forms towards conspecifics and heterospecifics were investigated. Workers of all three forms showed significant aggression toward non-nestmate (heterospecifics) in individual assay. In group assay, the mortality of ants were higher for monogyne S. invicta than for polygyne S. invicta after 24 h. These results showing that S. geminata has suffered the most mortality 24 h after inter-specific aggression tests. The outcome of these bioassay may be useful to predict the range expansion and species dominance of three fire ant forms. In addition, we measured the aggressive response of fire ants and to understand their aggressive threshold, potential shifts in populations and spatial distributions.

Little fire ant, *Wasmannia auropunctata*, established on Guam

Ross H Miller[1], Maia Raymundo[2]
[1]*University of Guam, Guam,* [2]*University of Guam, Guam*

Little fire ant (LFA), Wasmannia auropunctata, was detected on Guam in November 2011. Previous infestations in the Pacific Basin include the Hawaiian Islands of Hawaii, Maui and Kauai, New Caledonia, and Northern Queensland, Australia. All of these areas have air and sea connections to Micronesia. The devastating effects of LFA on agriculture and forest ecosystems observed in LFA infested areas are likely to occur on Guam and any other Micronesian island infested by LFA. LFA surveys on Guam suggest that it is presently established on at least seven sites on the island, including a green waste hardfill site of about 2 ha, and several small farms and residential areas. Impacts on invertebrate biodiversity have been noted in infested areas on Guam. The ants' spread to and throughout Guam is most likely due to human transport of infested plant material. Surveillance surveys suggest that it has yet to spread to the neighboring islands of the Commonwealth of the Northern Mariana Islands (CNMI), or elsewhere in Micronesia.

Introduced Asian paper wasp in New Zealand: Diploid males and triploid females production due to bottleneck *Harmonia axyridis* (Coccinellidae, Coleoptera)

Koji Tsuchida
Gifu University, Japan

Asian paper wasp Polistes chinensis is originally distributing around Far East Asia including Japan, Korean peninsula, and east shore of China. The species was accidentally introduced in New Zealand in 1979, and expands its distributing range. I analyzed and compare the population genetic structures between Japan and New Zealand using 10 microsatellite loci and mtDNA haplotypes. The results were as following, (1) although more than 95% of haplotypes were observed in the both countries, the remaining haplotypes was only observed in one of the two countries, (2) the genetic makeup in microsatellite loci in NZ was clearly different from that in Japan, (3) higher frequencies of diploid male and triploid female producing colonies were observed in NZ, suggesting that severe bottleneck operated during the introduction, (4) mean distance between mother and offspring in NZ was twice as large as that in Japan. Taken together, these results suggested that Asian paper wasp in NZ rushes around in North Island after passing through narrow gene flow.

The Potential geographical distribution of *Bactrocera correcta* (Diptera: Tephritidae) in China

Wenlong Ni[1], Zhihong Li[2], Jiajiao Wu[3], Yuliang Deng[4]

[1]China Agricultural University, China, [2]China Agricultural University, China, [3]Guangdong Entry-Exit Inspection and Quarantine Bureau, Guangzhou, China, [4]Xishuangbanna Entry-Exit Inspection and Quarantine Bureau, China

The guava fruit fly, Bactrocera correcta (Diptera: Tephritidae), is regulated as an important quarantine pest in China which invaded into Yunnan province recent years. The potential geographical distribution of B. correcta in China was researched using two suitability technical modes of 'CLIMEX + ArcGIS' and 'Suitability experiment + Suitability model + ArcGIS'. With the first mode, 28% areas of China which among the south part from Yangtze River is predicted as potential suitable region under current climate condition, and the suitable region percent will increase to 31% with the suitable range expanding northward to some parts Shandong Peninsula, Shanxi, Shaanxi and Gansu province under future climate condition in 2020, moreover, the suitable range will further increase to 34% with a geographical expanding to Hebei province and Shandong Peninsula in 2050. With the second mode, the eclosion rate model of B. correcta is established and the suitability of B. correcta is predicted with a legible trend from May to September with high degree. According to the eclosion rate model and suitability, 5 monitoring periods are suggested as (1) From Jan. To Dec.: Yunnan, Guangxi, Guangdong and Hainan. (2) From Mar. to Nov.: Sichuan, Guizhou, Hunan, Chongqing, Jiangxi. (3) From Mar. to Oct.: Hubei, Fujian, Taiwan, Shandong, Tibet, Shaanxi, Henan, Anhui, Zhejiang, Jiangsu and Shanghai. (4) From Apr. to Oct.: Xinjiang, Qinghai, Gansu, Shanxi, Hebei, Liaoning, Beijing, Tianjin. (5) From May to Sep.: Ningxia, Heilongjiang, Jilin, Inner Mongolia.

Invasive Species and Quarantine

Biological invasions and endosymbiosis in Arthropods, a case study: *Bemisia tabaci*

Helene Delatte[1], Nathalie Becker[2], Magalie Thierry[3], Jean-Michel Lett[4], Reynaud Bernard[5]

[1]CIRAD, Reunion, [2]MNHN, Reunion, [3]CIRAD, Reunion, [4]CIRAD, Reunion, [5]CIRAD, France

Biological invasions are more and more frequent worldwide and understanding this process is a big issue. Invasive success depends on several traits permitting local adaptation. Among those traits, host-plant adaptations or demographic advantages are specific traits involving in some cases endosymbiosis. Intracellular prokaryotic association known as endosymbiosis is a well known-phenomenon which is present at least in 15% of all insects. Among the sap-sucking insects of the suborder Sternorrhyncha, psyllids, whiteflies, aphids, and mealybugs, an obligatory endosymbiont is even crucial to allow them to synthesise essential amino acids. Furthermore, other non obligatory endosymbionts, so-called secondary endosymbionts, are known to be linked to adaptive traits which can enhance invasiveness of their host. These biotic interactions will be discussed through several models and in particular the invasive whitefly Bemisia tabaci. Indeed, two biotypes (B and Q) or "genetic species" of B. tabaci have a tremendous invasive success worldwide since the 80ies. They harbor a wide range of endosymbionts, with potentially 6 secondary endosymbionts (according to biotypes): Cardinium, Arsenophonus, Hamiltonella, Rickettsia, Wolbachia and Fritschea and one obligatory Portiera aleyrodidarum. Recent studies showed significant links between reproductive manipulations (strong female bias, non random hybridization), large fitness benefits, better thermotolerance or transmission efficiency of begomoviruses according to the endosymbionts of their infected hosts. Most of the functions of those secondary endosymbionts are described in other models, and are largely unknown yet in B. tabaci.

Effects of Behavior and Habitat Use on the Spread and Impact of Invasive Herbivores

David Crowder[1], Rami Horowitz[2], Yves Carriere[3]
[1]Washington State University, U.S.A., [2]Israel, [3]U.S.A

One of the most detrimental impacts of invasive species is the exclusion of native species, which reduces biodiversity and alters community structure. However, coexistence between invaders and native species might be promoted by niche partitioning, even when one species is excluded in some habitats. Here, we examined the effects of variation in species traits, behavior, and habitat use on patterns of coexistence or exclusion between invasive and native whitefly species in the Bemisia tabaci species complex. Species in this complex often engage in intense reproductive interference, with males attempting to mate with females of other species. In shared habitats, behavioral traits of invasive whitefly species allow them to more effectively locate and copulate with suitable mates, leading to faster rates of population growth and exclusion of native species. Under field conditions, however, native and invasive whitefly species that exclude each other in shared habitats often coexist. Using spatially-explicit models, we show that niche partitioning can promote coexistence between invasive and native whitefly across broad regions, despite asymmetric reproductive interference and exclusion in some habitats. Combining observational data from a long-term field study in Israel with model results indicated that variation in habitat use was a primary factor driving coexistence between invasive and native whitefly species across landscapes. Our study reveals how models can be linked with empirical data to isolate and test mechanisms underlying patterns of coexistence or exclusion following invasions.

Invasion of the horse-chestnut leaf miner in Europe: Implications at all trophic levels

Marc Kenis[1], Christelle Pere[2], Sandrine Girardoz[3]
[1]CABI Europe-Switzerland, Switzerland, [2]CABI Europe-Switzerland, Switzerland, [3]CABI Europe-Switzerland, Switzerland

The horse-chestnut leaf miner, Cameraria ohridella, is a moth that originates from the Balkans and has invaded most of Europe in about 20 years. In invaded ecosystems, biotic interactions occur at all trophic levels, with diverse consequences. The moth is a serious pest of horse-chestnut, Aesculus hippocastanum, an important ornamental tree in European cities. Although attacked trees do not die, they lose their amenity functions and, as a result, horse-chestnut is gradually replaced by other tree species. The moth also frequently oviposits on sycamore maple, Acer pseudoplatanus, but most larvae die within the first two instars. Attack rates and development success on maple greatly vary from tree to tree. During its invasion, C. ohridella has been adopted by a whole complex of natural enemies, in particular parasitoids, but these play a minor role in the population dynamics of the moth. In Europe, parasitism rates increase with host residence time and proximity to the region of origin, but not with increased biodiversity. Native leaf miners are significantly less abundant in the vicinity of horse-chestnut trees infested by C. ohridella compared to control sites, suggesting apparent competition mediated by shared natural enemies. However, so far, apparent competition through natural enemies has not yet been proven.

Invasive Species and Quarantine

Plant-mediated interactions between begomoviruses and invasive whiteflies

Junbo Luan[1], Xue-Ping Zhou[2], Shu-Sheng Liu[3]

[1]Zhejiang University, China, [2]Zhejiang University, China, [3]Zhejiang University, China

Plant-mediated interactions between begomoviruses and whiteflies exert important influences on the invasion of vectors and the epidemiology of plant diseases. Here, we summarize case studies on these types of interactions, and discuss the underlying mechanisms. Present studies show that such interactions can be mutualistic, neutral or negative. For example, infection of tobacco plants with Tomato yellow leaf curl China virus (TYLCCNV) largely increased the performance of two invasive putative whitefly species, Middle East-Asia Minor 1 (MEAM1) and Mediterranean of the Bemisia tabaci complex, but exerted no effect on the indigenous putative species, Asia II 1 and Asia II 3. Likewise, infection of tomato plants by tomato mottle virus had positive effects on MEAM1. In contrast, infection of tomato plants with TYLCCNV had no or only marginal effects on MEAM1 but decreased the performance of Asia II 3. Thus, it seems that positive effects of viruses on the whiteflies are more likely to occur in invasive species than in indigenous species. A recent research demonstrated that when tobacco plants were infected with TYLCCNV, the plant jasmonic acid defenses were repressed but significant changes in amino acid or sugar profiles were not detected, indicating that plant defenses play a major role in mediating the interactions in this system. As plant-mediated interactions between begomoviruses and whiteflies are so complex and variable, more case studies are needed to reveal general patterns of interactions. Furthermore, joined forces of molecular biologists and ecologists are required to reveal the molecular mechanisms in an ecological perspective.

Direct and Indirect Impacts of Infestation of *Myzus persicae* on *Bemisia tabaci*

Xiaoling Tan[1], Su Wang[2], Tongxian Liu[3]

[1]Northwest A&F University, China, [2]Beijing Academy of Agriculture and Forestry Sciences, China, [3]Northwest A&F University, China

The interactions between greenpeach aphid (Myzue persicae), sweetpotato whitefly (Bemisia tabaci) and tomato plants were determined through a combination of four factors: durations of aphid infestation (A), densities of aphids (B), intervals between aphid removal after different durations of infestation and at the time of whitefly release (C), and leaf positions on the plants (D). The results demonstrated that B. tabaci preferred to colonize the plants without aphid infestation when they have a choice. The plants with aphids had fewer whiteflies than the plants that were pre-infested by aphids for a certain period of time and then the aphids were removed. The whiteflies were able to colonize the plants on which aphids once infested, and were able to coexist with aphids if no uninfested plants were available. Direct intensive test revealed that infestation duration of the aphid had stronger defensive effects on whitefly infestation than the density of aphids, and the best combination of induced defense effects on whiteflies were 20 aphids feeding on the plant for 72 h. Indirect orthogonal assays reveal that the prime affected factor of whitefly preferring a host plant among several factors is (C) the interval . The importance of the four factors that affected the induced plant defense against whiteflies can bewas arranged in the following order: (C) > (B) > (A) > (D). In conclusion, the infestation of aphids at a certain density over a certain period of time triggered the plant's defensive system, and induced the plant to defend themselves against whiteflies.

Invasive Species and Quarantine

Global dynamics of the symbiosis between invasive ambrosia beetles, fungi and bacteria: Insights from high-throughput DNA sequencing

Jiri Hulcr[1], Nina R Rountree[2], Sarah E Diamond[3], Lukasz L Stelinski[4], Noah Fierer[5], Rob R Dunn[6]

[1]University of Florida, U.S.A., [2]North Carolina State University, U.S.A., [3]North Carolina State University, U.S.A., [4]University of Florida, U.S.A., [5]University of Colorado-Boulder, U.S.A., [6]North Carolina State University, U.S.A.

Ambrosia beetles, the increasingly damaging invasive insects, live in symbiosis with fungi. It has not been tested if the symbiosis also includes bacteria. We combined global sampling, insect anatomy, high-throughput sequencing of bacterial 16S, and multivariate statistics to comprehensively analyze prokaryotic communities in ambrosia beetle mycangium - the organ where beetles carry their symbionts. We tested whether 1) ambrosia beetles also host stable bacterial associates, and 2) whether these bacterial communities are more specific to beetle species or to locality of origin. We analyzed 6 beetle species (Dendroctonus frontalis, Xyleborus affinis, Xyleborus bispinatus-ferrugineus, Xyleborus glabratus, Xylosandrus crassiusculus, and Xylosandrus germanus) that represent 3 types of mycangia, and included five globally distributed species, and four species with major economic importance. Samples of 96 beetle mycangia yielded 1546 bacterial phylotypes. Several bacterial taxa appear to form the core microbiome of the mycangium. Three Mycoplasma (originally thought restricted to vertebrates), two Burkholderiales, and two Pseudomonadales are repeatedly present in mycangia worldwide across beetle species. However, no bacterial phylotypes were universally present, suggesting that ambrosia beetles are not obligately dependent on bacterial symbionts. The composition of bacterial communities is predicted by the host beetle species more than by the locality of origin, which suggests that dominant bacteria are horizontally transmitted rather than acquired from the environment. The invasive Xyleborus glabratus has a unique set of bacteria. We conclude that the mycangium hosts several horizontally transmitted bacteria such as Mycoplasma, most of which are likely facultative commensals or parasites.

A trial to evaluate a potential risk of tree-killing diseases by *Raffaelea*-ambrosia beetle complex

Naoto Kamata[1], Sunisa Sanguansub[2], Hideaki Goto[3]
[1]*The University of Tokyo, Japan,* [2]*Kasetsart University, Thailand,* [3]*Forestry and Forest Product Research Institute, Japan*

Tree-killing diseases caused by fungi Raffaelea spp. carried by ambrosia beetles are in epidemic in Japan, Korea, and the US. It is likely that invasion of ambrosia beetles in non-indigenous area promote potentially aggressive ambrosia beetle species to create new symbiotic relationship with fungi with high virulence. We determined ecological niche of ambrosia beetles on Qeurcus serrata and evaluated their risks in relation to potential invasiveness and aggressiveness to attack living trees. Freshly cut bolts were set on forest floor in three locations in Japan. Three niche contexts, timing of cutting tree, timing of starting exposure, and wood oldness, were artificially controlled by covering the bolts with metal mesh. Bolts were exposed to insect attacks for one month or until the end of September. The number of entry holes was used as an indicator for abundance of each species. Niche center and niche breadth were estimated for the three niche contexts. Scolytinae tended to show broader niche than Platipodinae. Furthermore, some Scolytid species have a habit of haplodyploidy and sibling mating. On the contrary, all Platypodinae species do not. Therefore, Scolytinae species are likely to have greater potential as alien species. Actually most of the invasive ambrosia beetles in the world belong to Scolytinae with one exception of Megaplatypus mutates. One the other hand, Platypodid species tended to attack fresh bolts compared to Scolytid so that Platypodid have higher risk to vector tree-killing disease than Scolytinae.

Impact of invasive insect herbivores on the foraging behavior of native parasitoids via changes in induced plant volatiles: A comparative study

Gaylord Desurmont[1], Matthias Held[2], Ted Turlings[3]

[1]University of Neuchatel Institute of Biology, Switzerland, [2]University of Neuchatel Institute of Biology, Switzerland, [3]University of Neuchatel Institute of Biology, Switzerland

Herbivore-induced plant volatiles often play an important role as cues in the foraging behavior of predators and parasitoids in search of prey or hosts. We propose that parasitoids can readily use plant-produced volatiles to distinguish between hosts and non-hosts, but that invading insect herbivores colonizing novel host plants may disrupt these finely-tuned interactions and negatively impact the foraging behavior of native parasitoids. Using Brassica rapa and its complex of native herbivores and parasitoids as a study system, we investigated the effect of two invasive herbivores (Spodoptera littoralis and Heliothis virescens) on the foraging behavior of 3 native parasitoids. In a 6-arm olfactometer setting, we simultaneously tested parasitoid attraction to plants (1) undamaged, (2) damaged by the parasitoid's host herbivore, (3) damaged by a native non-host, and (4) damaged by an exotic non-host. Overall, plants damaged by hosts were in general the most attractive to parasitoids, and undamaged plants the least attractive. Plants damaged by non-hosts showed intermediate levels of attractiveness, but there was no effect of the origin of the non-host (exotic or native) on attractiveness. H. virescens damage was found to cause more parasitoid attraction than S. littoralis damage, showing that invasive exotic herbivores may greatly differ in their impact on native parasitoids. In conclusion, these results demonstrate that invasive herbivores can impact infochemical networks between plants and natural enemies, but that invasive herbivores do not necessarily have a greater impact on specific plant-parasitoid interactions than other native herbivores.

Ecology and evolution of invasive plant species and their natural enemies

Arjen Biere[1], Jeff Harvey[2], Wim Van der Putten[3], Koen Verhoeven[4]

[1]Netherlands Institute of Ecology (NIOO-KNAW), Netherlands, [2]Netherlands Institute of Ecology (NIOO-KNAW), Netherlands, [3]Netherlands Institute of Ecology (NIOO-KNAW), Netherlands, [4]Netherlands Institute of Ecology (NIOO-KNAW), Netherlands

Introduced plants become dislocated from their co-evolved interactions with benefical and harmful insects in their native range, and engage in novel interactions in their new range. Biotic theories that try to explain why some introduced plants become invasive in their new range have stressed two benefits of this process for the plant: (1) Plants are released from many of the specialist insect herbivores that exerted top-down control in their native range (enemy release) and (2) When engaging in new interactions in their invaded range, plants benefit from their evolutionary novelty because insect herbivores in the invaded range are naive to their novel secondary metabolites (novel weapons hypothesis), unless they have preadapted to these chemicals on congeneric hosts present in the indigenous community. While some studies support the idea that plants benefit form their evolutionary novelty in the introduced range, there are numerous counter-examples where introduced plants are actually preferred by indigenous herbivores and biotic communities resist invasion of introduced species (biotic resistance). We argue that whether it is the plant or the insect that benefits from the plant's evolutionary novelty will much depend on the predominant mechanism underlying the interaction (e.g. detoxification- vs. recognition-based). Further, rapid evolutionary changes accompany many invasions. Enemy release has been assumed to facilitate an evolutionary shift in investment of resources from defenses against specialists to traits enhancing competition, reproduction, or generalist defense in the novel range (EICA). While support for this theory is mixed, we show some interesting examples compatible with this idea

Does mutualism drive co-invasion? The case of *Solenopsis invicta* (Hymenoptera: Formicidae) and *Phenacoccus solenopsis* (Hemiptera: Pseudococcidae)

Aiming Zhou[1], Yongyue Lu[2], Ling Zeng[3], Yijuan Xu[4], Guangwen Liang[5]

[1]South China Agricultural University, China, [2]South China Agricultural University, China, [3]South China Agricultural University, China, [4]South China Agricultural University, China, [5]South China Agricultural University, China

Despite mutualism between ants and honeydew-producing hemipterans has been extensively recognized in ecosystems biology, there have been few attempts to test this hypothesis that mutualism between two alien species drive their co-invasion. We try to clarify whether the interactions between S. invicta and P. solenopsis could facilitate mutual population growth and invasive ability. Overall, our results suggest that the mutualism between S. invicta and P. solenopsis facilitate the population increase and fitness of each other. Although native ants may also set up such relationship with P. solenopsis, S. invicta tends to occupy much more honeydew and therefore play a predominant status. Compared with native ants, S. invicta has stronger mutualism with P. solenopsis, which may facilitate their invasion in South China and ultimately achieve co-invasion.

Will Access and Benefit Sharing procedures impede biological control: The problem

Barbara I. P. Barratt[1], Jacques Brodeur[2]
[1]AgResearch, New Zealand, [2]Universite´ de Montreal, Canada

The objectives of the Convention on Biological Diversity (CBD) are the conservation of biological diversity, the sustainable use of its components (genetic resources) and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources. The CBD also recognises the sovereign rights of States over their genetic resources, and the authority to determine access to genetic resources rests with the national governments. In the past, gaining access to biological control agents depended on goodwill, reciprocal arrangements, collegiality, minimal bureaucracy, spirit of sharing of biological control agents and knowledge. In the future biological control may have to comply with the access and benefit-sharing (ABS) regime that is agreed. These issues will be introduced and discussed.

New Access & Benefit Sharing regulations: Is there a future for the biocontrol industry?

Johanna Klapwijk
Koppert Biological Systems, Netherlands

The Convention on the Biodiversity (1992) gives countries the sovereign right over their genetic resources and the right to develop their own regulations for sharing of benefits arising out of utilization of these resources. After the Access & Benefit Sharing Protocol has been agreed in Nagoya in 2010 an increasing number of countries is implementing regulation on ABS, resulting in limited access to new biocontrol agents. This is threatening existing IPM programs as new pests from all over the world are invading agricultural systems and control strategies against these pests have to be compatible with biocontrol strategies against other pests. If a compatible solution is not found in time, chemical intervention will put an end to existing IPM programs. As the biocontrol industry is a small and relatively unknown sector, time and effort to come to agreements on ABS may be unproportionally high and biocontrol companies may decide not to continue investigating a potentially interesting natural enemy. Benefit sharing will increase the cost price of products directly when monetary benefits on the products have to be shared, but also indirectly due to increased administration. Since profit margins in the biocontrol industry are already low, these extra regulations on ABS may put an end to a part of the biocontrol companies. Awareness raising on national decision making level is required to show the impact of strong ABS regulation on biological control and thus on the production of safe food.

The current status of the conflict between ABS and insect-resource industrialization in Korea

Ohseok Kwon
Kyungpook National University, Republic of Korea

The recent agreement of ABS (Access to genetic resources and Benefit Sharing) at Nagoya in 2010 requires further action plans by member states to setup PIC (Prior Informed Consent) and MAT (Mutually Agreed Terms) regulations. The Korean government is now preparing the ABS law to be enacted by the end of 2012. The discusssion of how this new regulation will affect the introduction of exotic species including natural enemies of the pest insects as well as the effort for industrialization of insects as biological resources is presented. The legal conflicts among the different governmental institutions in Korea are given an account, and the possible solution is suggested.

Access and benefit sharing - a growing challenge for biological control in Europe?

Franz Bigler[1], Matthew J. Cock[2], Karel Bolckmans[3], Joop C. van Lenteren[4]
[1]Agroscope, Switzerland, [2]CABI, Switzerland, [3]Koppert B.V., Netherlands, [4]Wageningen University, Netherlands

Exploration for natural enemies, usually in the area of origin of an accidentally introduced pest, and subsequent release in new areas of the pest is the basis for successful biological control independent of whether the biological control agents (BCAs) are applied in inoculative or augmentative control programs. Europe has long been an important exporter of natural enemies for classical biological control. However, over the last decades, Europe has become an increasing importer of BCAs for augmentative use against alien pests. Of the 230 invertebrate species that are commercially available worldwide for augmentative biological control, 170 species are used in Europe. Recent applications of Access and Benefit Sharing (ABS) legislation under the Convention of Biological Diversity have made it impossible or difficult to study, collect and export new natural enemies in certain countries. If the ABS principles are widely applied in this way, biological control will be seriously hampered in Europe. This is particularly the case if the alien pest species originates in a country that applies the ABS rules for BCAs in the expectation of monetary benefit sharing. Whereas it is not expected that the application of ABS procedures will become a significant barrier to the export of BCAs from Europe, European countries are likely to expect documentation that ABS in the source country has been addressed in order to permit importation of BCAs. In the presentation we summarize our concern about the actual and potential adverse effects of ABS rules on the future of biological control in Europe.

The effects of Access and Benefit Sharing (ABS) on the utilization of biological control in Brazil

Jose Roberto Postali Parra
ESALQ/Universidade de Sao Paulo, Brazil

Brazil has Biological Control Programs comparable to the best one's of the world. In sugarcane, insect pest control is done by using micro or macroorganisms in almost half of the cultivated area. Cotesia flavipes and Trichogramma galloi are released in around 3,500,000 ha to control the sugarcane borer, Diatraea saccharalis, and the fungus Metarhizium anisopliae is sprayed in around 2,000,000 ha to control the froghopper, Mahanarva fimbriolata. However, other Classical or Applied Biological Control programs, using exotic natural enemies, like C. flavipes were also developed in Brazil. There are good results against pests to cassava, soybean, corn, wheat, vegetables, citrus, forestry and pastures. We will discuss the effects of ABS, especially after the Nagoya Convention on the utilization of Biological Control in Brazil.

Access and Benefit Sharing: Will taxonomic research be facilitated or not?

Andrew M. R. Bennett[1], Jeffrey Hunter Skevington[2], Frederic Beaulieu[3], Peter G. Mason[4]

[1]Agriculture and Agri-Food Canada, Canada, [2]Agriculture and Agri-Food Canada, Canada, [3]Agriculture and Agri-Food Canada, Canada, [4]Agriculture and Agri-Food Canada, Canada

In 2010, the Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits (ABS) was adopted at the tenth meeting of the Conference of the Parties in Nagoya, Japan. For taxonomy, the collection and exchange of specimens in all regions is critical for comprehensive and thorough treatments of biodiversity. Informed ABS policy across countries will be key to ensure that taxonomic research is enabled. Thus, development of recommendations to guide governments when developing ABS policy is paramount to facilitate continued taxonomic research worldwide.

Challenges for the biological control sector in the implementation of the Nagoya Protocol

Marie Schloen[1], Jacques Brodeur[2]
[1]*University of Bremen, Germany,* [2]*Universite de Montreal, Canada*

Over the last years, a new international legal architecture on access and benefit-sharing (ABS) for genetic resources has emerged, which have important implications for biological control. The recently adopted Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization to the Convention on Biological Diversity constitutes the newest element of this legal framework and adds new impetus to the discussion about how to best address ABS for biological control. The Nagoya Protocol (2010) provides some opportunities to accommodate the special features and needs of biological control in addressing ABS. For example, it requires Parties to consider the importance of genetic resources, including natural enemies, and their special role for food security in the development and implementation of access and benefit-sharing legislation or regulatory requirements. Parties shall also encourage the development and use of sectoral and cross-sectoral model contractual clauses for mutually agreed terms and of voluntary codes of conduct, guidelines, best practices and standards in relation to ABS. Furthermore, the Protocol foresees that in its implementation due regard should be paid to relevant ongoing work or practices under other international instruments and organizations, and opens the possibility for the development of specialized ABS approaches for certain genetic resources or types of uses. Climate change and biological control: State of knowledge, risks and opportunities

Philippa Jane Gerard[1], Matthew J.W. Cock[2], David R Gillespie[3]
[1]AgResearch, New Zealand, [2]CABI Europe, United Kingdom, [3]Agriculture and Agri-Food Canada, Canada

A scoping study was undertaken in 2011 for the CGRFA at FAO to ascertain how climate change is likely to affect the use of beneficial invertebrates that are integral to food security and agricultural production. Here we summarise the key findings in regard to the natural enemies that regulate pest populations, with selected case studies. Parasitoids and predators are more likely to be affected by climate change than herbivores because they depend on the capacity of the lower trophic levels to adapt to these changes.In continental regions, most natural enemies will have little difficulty tracking their hosts/prey at predicted range shifts but soil-dwelling and flightless groups may not move as readily and oceanswill prove effective barriers. Therefore, there will be increased demand for biological control agents, especially in island states. Climate change can disrupt the stability of biological control systems through loss of synchrony arising from changes in developmental rates and when species have different initiators of reproductionand diapause. The increasing occurrence of extreme events (heat waves, floods, drought, and unseasonal cold) has the potential to disrupt biological control food webs independently of the disruption of cropping systems. Many classical biological control introductions have been based on few individuals and selection/ introduction of adapted strains to increase genetic diversity may assist system robustness.Genetic diversity of biological control agents can only be satisfactorily maintained in situand the most important reservoirs are agro-ecosystems that favour natural diversity, especially in regions where wild crop progenitors or early domesticated crop lines still persist.

The harlequin ladybird, Harmonia axyridis, is an alien in Europe and many other parts of the world where it affects other species of ladybird through competition for food and intra-guild predation. We developed a method to assess which native ladybird species are most at risk following the invasion of H. axyridis. The three components of the risk assessment are: the likelihood that the assessed native species encounters H. axyridis in the field, evaluated through co-occurrence indices; the effect on native species through competition for food; the effect on native species through IGP. Native ladybirds were scored, for each component, on a three-point scale and the final risk was calculated by multiplying the likelihood of encounter with the sum of the two impact scores. Thirty native European species were assessed through data obtained from field observations, laboratory experiments and literature reviews. Four species obtained the maximum score and are thus considered most at risk: Adalia bipunctata, Adalia decempunctata; Calvia decemguttata and Oenopia conglobata. These species are usually found on deciduous trees, which is the preferred habitat of H. axyridis, have immature stages which are highly vulnerable to intra-guild predation by H. axyridis and are primarily aphidophagous. This risk assessment method could be applied to other invasive alien predators which are considered a threat to other native species through competition and predation.

Does knowledge of natural host range always help predict host range in new areas of introduction? A case study with the braconid parasitoid *Microctonus aethiopoides* Loan

Barbara I. P. Barratt[1], Rolf G. Oberprieler[2], Diane M. Barton[3], Mohamed Mouna[4], Mark Stevens[5], Miguel A. Alonso-Zarazaga[6], Cor J. Vink[7], Colin M. Ferguson[8]

[1]AgResearch Invermay, New Zealand, [2]CSIRO, Australia, [3]AgResearch Invermay, New Zealand, [4]Universite Mohammed V-Agdal, Morocco, [5]Yanco Agricultural Institute, Australia, [6]Museo Nacional de Ciencias Naturales, Spain, [7]AgResearch Lincoln, New Zealand, [8]AgResearch Invermay, New Zealand

Information on natural and novel host range of proposed biological control agents can help to inform predictions of potential host range in new areas of introduction. A retrospective study was conducted to compare the natural host range of Microctonus aethiopoides Loan (Hymenoptera: Braconidae) with its novel host range found in Australia and New Zealand, where it has been introduced to control the adult stage of the weevil Sitona discoideus Gyllenhal (Coleoptera: Curculionidae), a pest of lucerne. The host ranges determined from field surveys in Australia and Morocco were compared with field host range in New Zealand. In Morocco, species in the genera Sitona and Charagmus (Curculionidae: Entiminae: Sitonini) and Hypera (Curculionidae: Hyperinae: Hyperini) were found to be parasitised by M. aethiopoides. In Australia, non-target parasitism of 'Prosayleus' sp. 2 (Curculionidae: Entiminae: Leptopiini) was the only non-target host found for M. aethiopoides. In New Zealand 19 native and introduced weevil species have been recorded as hosts of M. aethiopoides, mainly in the subfamily Entiminae (tribe Leptopiini) but also in Curculioninae, Cyclominae and Lixinae. This is discussed in the context of predictions that could have been made at the time of introduction 30 years ago had the Moroccan and Australian data, modern molecular technologies and current understanding of weevil classification been available. The absence of Leptopiini in Morocco and the record of a native Australian leptopiine host could have indicated that native weevils in this tribe in New Zealand might be at risk of attack by M. aethiopoides.

Assessing risks of post-introduction shifts in host specificity of parasitoids introduced to control aphids

Keith R Hopper
USDA-ARS, U.S.A.

Assessing the risks of post-introduction shifts in host specificity of parasitoids introduced for biological control is crucial for the safety of introductions. Assessments are based on reviews of the literature on host specificity and candidate biology, field evaluations of host specificity in the region of origin, and quarantine experiments. Each of these approaches has its strengths and weaknesses. Using assessments of risks of host shifts in Aphelinus species proposed for introduction against aphids, I discuss ways to improve assessment of the risks of host shifts, with an emphasis on quarantine experiments. Host specificity shifts may be behavioral or genetic, and experiments have allowed us to assess the risks of both types of shift. Surprisingly, host specificity does not appear to be behaviorally dynamic, at least in Aphelinus species with narrow host ranges. On the other hand, laboratory selection gave a more rapid shift in host specificity than we had expected. Analysis of the genetic architecture should provide better understanding of the risks of evolutionary host shifts.

Biological Control and the carbon cycle

George Eugenio Heimpel
University of Minnesota, U.S.A.

Biological control can lead to decreases in the use of pesticides and therefore reduced carbon emissions associated with pesticide manufacture, transport and application. I present an analysis of the extent to which naturally-occurring biological control of the soybean aphid, Aphis glycines, leads to reductions in carbon emissions in the United States. I also report calculations for carbon emission reductions associated with selected classical biological control projects. Finally, I discuss the potential role of classical biological in the carbon cycle more generally, including effects on carbon sequestration.

Brown marmorated stink bug, *Halyomorpha halys* (Stal): Impact of an Asian species introduced into North America

Tracy C Leskey[1], Anne Nielsen[2]
[1]*USDA ARS, U.S.A.,* [2]*Department of Entomology, U.S.A.*

The brown marmorated stink bug (BMSB), Halyomorpha halys (Stal) is an insect native to China, Taiwan, Korea, and Japan accidently introduced into the United States sometime in the mid- to late 1990s that has emerged as a pest of unprecedented importance to agriculture. Currently, BMSB is well established throughout DE, MD, PA, NJ, VA and WV and has been officially detected in over 35 states in the U.S. and recently in Ontario, Canada. BMSB is considered a polyphagous pest of many specialty crops in Asia including tree fruit, vegetables, shade trees and leguminous crops with specific mention of apple, cherry, peach, and pear. After detection, localized reports of problems were reported in and near Allentown, PA in the early 2000s. However, in 2008, BMSB populations increased dramatically and by 2010 attacked many specialty and row crops in the mid-Atlantic region of the United States. In apple alone, BMSB is estimated to have caused $37 million dollars in damage. In addition, this insect is a serious nuisance pest, as overwintering populations will move to human-made structures. In order to combat this serious pest, a large team comprised of researchers from 14 institutions in 10 states in the U.S. was rapidly assembled and is currently developing monitoring tools and management strategies for a variety of cropping systems.

Observations on current and future *Drosophila suzukii* distribution, impact and management in the United States

Vaughn Walton[1], Hannah Burrack[2], Rufus Isaacs[3], Peter Shearer[4]

[1]Oregon State University, U.S.A., [2]North Carolina State University, U.S.A., [3]Michigan State University, U.S.A., [4]Oregon State University, U.S.A.

Drosophila suzukii, Spotted Wing Drosophila, is a pest of fresh commercial stone and small fruit in the United States of America. It was recorded in commercial crops in Pacific production areas during 2009. Subsequent recordings of D. suzukii and fruit damage associated with this pest were made in all major Pacific, Midwest and Atlantic fruit production areas. The distribution and impact of D. suzukii on various fruit industries in each of these regions will be discussed. Key differences of D. suzukii seasonal phenology and damage on selected crops will be described for each of these production regions. The currently used methods to manage D. suzukii, and how management between areas may differ will be discussed. Promising future management strategies of this pest will be elucidated.

Urban and agricultural impact of *Megacopta cribraria* in the southeastern United States

Michael Dennis Toews[1], Tracie Jenkins[2], Dan Suiter[3], Phillip Roberts[4], David Buntin[5], John All[6], Stormy Sparks[7], John Ruberson[8], Wayne Gardner[9]

[1]University of Georgia, U.S.A., [2]University of Georgia, U.S.A., [3]University of Georgia, U.S.A., [4]University of Georgia, U.S.A., [5]University of Georgia, U.S.A., [6]University of Georgia, U.S.A., [7]University of Georgia, U.S.A., [8]University of Georgia, U.S.A., [9]University of Georgia, U.S.A.

In October 2009, Megacopta cribraria (Heteroptera: Plataspidae) was discovered aggregating on south and east facing exterior surfaces of buildings in Georgia, United States. This invasive insect was previously unknown to the Western hemisphere. The insect is native to Asia where its preferred host is kudzu (Pueraria spp.). In a little more than two years, the distribution has spread to nearly all of Georgia and South Carolina, and parts of Alabama, North Carolina, and Virginia. Genetic analyses from the entire North American population suggest a single maternal lineage. Starting in 2010, large populations were observed on soybean, Glycine max, where an entire generation was completed. Populations in soybean can exceed 100 individuals per sweep and inflicted an average yield loss of 37% compared to adjacent plots that were treated with insecticides to prevent M. cribraria colonization. Studies in Georgia show that there are at least two generations and three distinct periods of adult flight activity per year. During the spring and fall, M. cribraria is a serious urban nuisance as it flies to and lands on light colored surfaces including people, homes, and automobiles. The pest gives off a strong odor when disturbed and crushing on human skin will result in localized itching and skin whelps. Continued range expansion is expected.

Asian citrus psyllid and Huanglongbing in the New World: Impact and anagement

Philip A. Stansly[1], Jawwad A. Qureshi[2]
[1]*University of Florida, U.S.A.*, [2]*IFAS, U.S.A.*

Citrus evolved in Asia, and so too have many of its diseases, pests and their natural enemies. These include huanglongbing (HLB), its psyllid vector Diaphorina citri, and the parasitoid Tamarixia radiata. Little attention was paid in 1942 to the first record of D. citri in Brazil, but the discovery there of huanglongbing 62 years later, followed by Florida in 2005, marked the beginning of radical changes to the citrus industry. Intensified insecticidal control and plant nutrition, coupled with protected nursery production and roguing of infected trees, have been moderately effective in managing the disease but greatly increased production costs. Vector control is key, even in infected orchards, and has proven more efficient in large production units, leading toward consolidation and/or coordinated area wide sprays. However, problems of secondary pest resurgence signal the need for an integrated approach employing cultural methods and selective, even threshold driven applications that conserve natural enemies and may open the door for augmentative biological control. Progress toward these goals include: sprays directed at adult psyllids during plant dormancy that spare many beneficial insects, an efficient sampling method, the "stem tap" to quickly assess psyllid populations, organization of mass rearing facilities for T. radiata, and a growing number of available selective insecticides. With these tools in hand, the industry can survive while awaiting a genetic "magic bullet" to wipe out HLB.

Monochamus species as potential vectors of the pine wood nematode in Europe : What can be learnt from the Asian situation ?

Geraldine Roux[1], Edmundo Sousa[2], Juan Alberto Pajares Alonso[3], Alain Roques[4]

[1]INRA Orleans, France, [2]INRB, Portugal, [3]UVA, Spain, [4]INRA Orleans, France

The worldwide genus of long-horned beetles, Monochamus, has drawn a particular attention because several species are known to be a vector of the Pine Wood Nematode (PWN), Bursaphelenchus xylophilus, carrying and transferring the nematode to conifer host trees. Although not a pest in its native North American range, PWN has devastated forests in Asia, and more recently in Europe. The five Monochamus species recorded in Europe, i.e. M. galloprovincialis, M. sutor, M. sartor, M. urussovi and M. saltuarius, may represent potential vectors for PWN. However, only M. galloprovincialis has been proved so far to be associated with PWN invasion of Portugal and Spain. This talk will review the European Monochamus species, with a special focus on their geographic distribution range and ecological requirements. A state-of-the-art of the present situation of pine wilt disease in Europe will be presented, and the potential vectoring role of the different Monochamus species throughout Europe will be evaluated with regard to the situation in Asia. Finally, we will present the ongoing European project REPHRAME that is bringing together Europe's leading experts on PWN, together with colleagues from around the world, to address the key gaps in current knowledge of pine wilt disease and its associated organisms.

Keywords:*Monochamus species, Pine Wood Nematode, Europe, REPHRAME*

Asian soybean aphid in North America ? Invasion and classical biological control

George Eugenio Heimpel[1], Keith R. Hopper[2], Rosanna Giordano[3], Kim Hoelmer[4], Kongming Wu[5], Joon-Ho Lee[6]
[1]University of Minnesota, U.S.A., [2]U.S. Dept. of Agric., U.S.A., [3]University of Illinois, U.S.A., [4]U.S. Dept. of Agric., U.S.A., [5]Chinese Academy of Agricultural Sciences, China, [6]Seoul National University, Republic of Korea

The soybean aphid, Aphis glycines, is native to eastern Asia and was first found in North America in the year 2000. We discuss molecular data regarding the Asian provenance of soybean aphid in N. America and also the possibility of more than a single invasion. Soybean aphid requires shrubs in the genus Rhamnus to overwinter, and its invasion was facilitated by the previous invasion of Rhamnus species from Europe and Asia. Also, the presence of soybean aphid in North America is likely facilitating the spread of non-native aphid consumers such as the multicolored Asian ladybeetle, Harmonia axyridis. Together, the network of interactions among introduced species linked to soybean aphid may be considered an 'invasional meltdown'. Classical biological control of soybean aphid using Asian parasitoids is underway and we discuss these intentional introductions in light of the unintentional introduction of a parasitoid ? Aphelinus certus ? that is attacking soybean aphid.

The citrus flatids, *Metcalfa pruinosa*, recent outbeak in the Korean Peninsula

Seunghwan Lee[1], Minyoung Kim[2]
[1]*Seoul National University, Republic of Korea,* [2]*Seoul National University, Republic of Korea*

The citrus flatid planthopper, Metcalfa pruinosa (Say 1830) (Hemiptera: Flatidae), has a native distribution in eastern North America, It has recently invaded Italy in 1979 and has since spread to other European countries. In 2009, Metcalfa pruinosa was discovered in Seoul and the Gyeonggi Province, Republic of Korea. This is the first record in the eastern part of Palaearctic. One year after its discovery, in July 2010, we found significant populations and serious damage on many deciduous forest trees, ornamental trees, and agricultural crops in central regions of the Korean Peninsula. In this paper, we report the status of the outbreak and discuss the biology, morphological characters, distribution, host plants, and the importance of M. pruinosa as a potential insect pest in the Korean Peninsula.

Invasion of leafminers, *Liriomyza* spp. (Diptera: Agromyzidae), in the eastern Palearctic region

Yoshihisa Abe
Kyushu University, Japan

Liriomyza sativae Blanchard, L. trifolii (Burgess) and L. huidobrensis (Blanchard) (Diptera: Agromyzidae) are indigenous to the New World, but they have established populations in the eastern Palearctic region in the last two decades. These three species are polyphagous herbivores that are important pests of numerous vegetable and ornamental crops. Two of the most important of them, L. sativae and L. trifolii, have been introduced into the same geographic areas and species displacement between these two species has been observed. In Hainan Island, China, L. trifolii replaced L. sativae as the predominant leafminer of vegetables, as in the western USA in the 1970s. However, in Japan, L. trifolii was displaced by L. sativae. In Hainan Island, where the management of Liriomyza depends mainly on chemical insecticides, the rapid displacement of L. sativae by L. trifolii can be attributed to the lower insecticide susceptibility of L. trifolii. In contrast, the displacement in the opposite direction in Japan is probably due to the higher fecundity of L. sativae and differential effects of the introduced natural enemy Dacnusa sibirica Telenga (Hymenoptera: Braconidae). In winter, L. sativae and L. trifolii are found only in greenhouses in Japan, and D. sibirica is a more effective parasitoid at low temperatures. When growers in Japan find the mines induced by Liriomyza on vegetables in greenhouses in winter, they usually use D. sibirica to control the leafminers. This parasitoid can control L. trifolii effectively, but cannot control L. sativae.

Invasion of exotic gall midges in East Asia

Heung-Sik Lee[1], Tae-Jun Kang[2], Ki-jung Hong[3]

[1]Animal Plant and Fisheries Quarantine and inspection Agency, Republic of Korea, [2]Rural Development Administration, Republic of Korea, [3]Animal Plant and Fisheries Quarantine and inspection Agency, Republic of Korea

Recentry, the gall midges, which invaded in to Korea, severely damaged on plants in agriculture and forest. Five invasive gall midges are economically important, and the information on their biological features, invasive pathways and economic impact is provided. Pine gall midge introduced from Japan. It have spreaded from Mokpo in southwestern port, distributed nationwide in present. It damaged on Korean red pine and black pine, prevention cost was needed each year. It is very important pest in Korean pine tree. The black locust gall midge was discovered in 2001 for the first time in Korea and have spread into all Korean peninsular and Jeju island. According to Dr. Yukawa, its origin is USA in North America, and invaded into countries where USA troop stationed, as like Japan and Korea in Asia, and Balkan peninsula in Europe. The orchid gall midge was occurred in greenhouse for Dendrobium spp. occasionally. It attacked on flower buds and they were rotted and dropped into ground. It was introduced through young seedlings from Thailand. After control by insecticide, the orchid gall midge were eradicated in greenhouse in which the orchids were damaged. Last, the blueberry gall midge was newly invaded into Korea. It is major pest for Vaccinium spp, its origin is eastern USA. Its pathway was suspected because of many seedlings. The monitoring and fast control is more important at post quarantine, to prepare increase of trade of agricultural commodity after FTA with other countries.

Dispersal patterns of exotic forest pests in South Korea

Won Il CHOI[1], Young-Seuk Park[2], Sang-Hyun Koh[3]

[1]Korea Forest Research Institute, Republic of Korea, [2]Korea Forest Research Institute, Republic of Korea, [3]Korea Forest Research Institute, Republic of Korea

Invasive species have potentially devastating effects on ecological communities and ecosystems. To understand the invasion process of exotic forest pests in South Korea, we reviewed four major species of exotic forest pests: the pine needle gall midge (Thecodiplosis japonensis), pine wilt disease caused by the pine wood nematode (Bursaphelenchus xylophilus), the fall webworm (Hyphantria cunea), and the black pine bast scale (Matsucoccus thunbergianae). We consider their biology, ecology, invasion history, dispersal patterns and related traits, and management as exotic species. Among these species, the dispersal process of fall webworm was linear, showing a constant range expansion as a function of time, whereas the other three species showed biphasic patterns, rapidly increasing dispersal speed after slow dispersal at the early invasion stage. Moreover, human activities accelerated their expansion, suggesting that prevention of the artificial movement of damaged trees would be useful to slow expansion of exotic species. We believe that this information would be useful to establish management strategies for invasion species.

The status quo of invasive alien insects species and plant quarantine in Korea

Ki-Jeong Hong[1], Jong-Ho Lee[2], Gwan-Seok Lee[3], Seunghwan Lee[4]

[1]MIFFAF, Republic of Korea, [2]MIFFAF, Republic of Korea, [3]RDA, Republic of Korea, [4]Seoul National University, Republic of Korea

The recent increasing agricultural commodities from abroad and travelers with the economic growth in Korea and globalization have resulted in an exponential increase in the number of invasive alien insect species establishing in Korea. When the 'alien' is defined as the species introduced after the beginning of the Greater Korean Empire Era (1897), a total of 171 insect species is proposed as invasive alien species. From this study, on average, 0.85 alien insect species has become established each year for the last 40 years, and 76.6% of the alien insect species were economic agricultural pests. The annual invasion rate and the pest interceptions from imported cut flowers, planting materials, and vegetables have been rapidly increasing. Passengers' baggage is an important pathway for fruit flies. Most of the alien pests that were first found in Japan were confirmed in Korea at least 3 years later until the 1990s, but the pattern has been often reversed since the 2000s. So the continuous information sharing with neighboring countries like Japan and China is needed to develop the system for early detection and prompt action against invaders.

Biological control options of the invasive tomato pest *Tuta absoluta*

Alberto Urbaneja[1], Nicolas Desneux[2]

[1]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain, [2]French National Institute for Agricultural Research (INRA), France

The South American tomato pinworm, Tuta absoluta (Meyrick) (Lepidoptera: Gelechiidae) is one of the most devastating pests in tomato crops. In the absence of control strategies, damages in tomatoes (Lycopersicon esculentum) can reach 100%. Although originally from South America, T. absoluta was detected in eastern Spain at the end of 2006, and in the following years in main Mediterranean coastal tomato-producing areas (and more generally Europe) with populations quickly reaching damaging levels. This occurred despite plant protection agencies' efforts, demonstrating how fast T. absoluta populations can build up when resources are available. In newly infested areas, T. absoluta is especially problematic during the first years of its presence. Nevertheless, after two to three years in certain areas, the incidence of T. absoluta has become less severe. There are several factors contributing that explain this reduction in T. absoluta's incidence, such as an increase in farmers' and producers' knowledge of pest behavior and biology and the correct application of integrated pest control strategies. The impact of opportunistic native natural enemies (fortuitous biological control) should be considered as one of the key factors in this reduction. Furthermore, successful biological control programs based in the use of predatory mirids (Hemiptera: Miridae) have contributed not only to manage T. absoluta but also other important pests of tomato such as whiteflies. This strategy has been successfully implemented in more than 6000 ha of commercial greenhouses in the Mediterranean basin.

Introduction of natural enemies against exotic insect pests in Japan

Eizi Yano
Kinki University, Japan

Exotic natural enemies have been introduced for controlling exotic pests after the world war in Japan. Some species have been introduced for the classical biological control of introduced pests of fruit trees. Successful examples are introduction of two aphelinid parasitoids, Aphytis yanonesis and Coccobius fulvus against the arrowhead scale, Unaspis yanonensis, a scale insect attacking citrus trees, and that of a torymid parasitoid, Torymus sinesis against the chestnut gall wasp, Dryocosmus kuriphilus. Protected culture has been developed dramatically in Japan in 1960s. Many exotic species or strains of arthropod pests infesting greenhouse vegetables have invaded with the increase of international trade of seedlings. Most of them are small in size but highly reproductive and easily develop resistance to pesticides. The most serious groups are whiteflies, e.g. Bemisia tabaci type B and Q, Trialeurodes vaporariorum, and thrips, e.g. Thrips palmi, and Frankliniella occidentalis. Aphelinid parasitoids, Encarsia formosa, Eretmocerus eremicus and Eretmocerus mundus and a predatory bug, Amblyseius swirskii have been introduced to control whiteflies. A predatory mite, Neoseiulus cucumeris has been introduced to control thrips. Commercial augmentative release of these species is carried out in greenhouses. They have been commercialized in Europe and imported by trading companies. These exotic whiteflies and thrips transmit virus diseases of some greenhouse crops, which hamper biological control of these pests using natural enemies. Present major concerns about importation of exotic natural enemies are their environmental impact and the procedure of access and benefit sharing.

Climate change and pest risk analysis

Kyla Jane Finlay[1], Jo Elizabeth Luck[2]
[1]*CRC Plant Biosecurity Australia, Australia,* [2]*CRC Plant Biosecurity, Australia*

Projected climates are predicted to influence the growth, development and behaviour of pest and pathogens necessitating the revision of current biosecurity practices such as preparedness, prevention, and containment policies and trade / market access issues. A review led by the Quadrilateral Biosecurity Climate Change Working Group considered the implications of climate change on biosecurity policy and recommended that a template be developed for incorporating climate change projections into Pest Risk Analysis (PRA) to enhance biosecurity decisions. PRA's involve pest identification; pest risk assessment (categorisation, assessment of probability of entry, establishment and spread, assessment of consequences) and pest risk management. We discuss the key elements required to incorporate the consideration of climate change into PRA's with the view for developing a prototype template for use in biosecurity policy arenas. Also discussed are procedural guidelines for possible inclusion such as the use of a standard climate change emission scenario, nominating a specified time horizon (eg 2020-2030 as opposed to longer range forecasts) and consideration of the climate change parameters to be included. Projections of future climate trends indicate that the nature, extent and intensity of climatic change will vary spatially and temporally. Responses of pests and pathogen to these changes are expected to be species and region-specific and made more complex by their interactions and interdependencies. Determining the effect of climate change on pest risk analyses will lead to new directions in biosecurity management and implications for biosecurity policy benefiting by directing scarce resources where they are most required.

Invasive Species and Quarantine

Lessons from the global eradication and response database

David Maxwell Suckling[1], John M Kean[2], Lloyd D Stringer[3], Patrick C Tobin[4], Dan A Herms[5], Danny C Lee[6], Deborah G McCullough[7], Therese Pluess[8], Takehito Yamanaka[9]

[1]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [2]AgResearch, New Zealand, [3]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [4]US Forest Service, U.S.A., [5]The Ohio State University, U.S.A., [6]US Forest Service, U.S.A., [7]Michigan State University, U.S.A., [8]University of Fribourg, Switzerland, [9]National Institute for Agro-Environmental Sciences, Japan

A database of insect and plant pathogen eradication programs has been developed currently, with 916 incursion responses, including 855 eradication programs from 103 countries, documented with 580 references. Of these, 143 arthropods were targeted in 669 eradication programs in 91 countries, with a surprisingly high rate of 280 eradications (intentional local extinctions) confirmed, 98 known failures, 8 false declarations of success and 85 programs in progress (86 of unknown outcome). The most frequent targets were gypsy moth (73), medfly (57), Oriental fruit fly (40), yellow fever mosquito (33) and emerald ash borer (25). Many lessons can be learned from a historical analysis of the targets and technologies used, including surveillance systems and eradication tools. This paper will present a range of analyses from the database that support the proposition that insect eradication is often possible and cost effective for organisms where the alternative is significant long-term ongoing costs.

A immunomodulatory protein RH-p36 is relating to hard tick blood-feeding success and oviposition

Jinlin Zhou[1], Xiaojuan Lu[2], Fengxun Guo[3]

[1]Chinese Academy of Agricultural Sciences, China, [2]Chinese Academy of Agricultural Sciences, China, [3]Chinese Academy of Agricultural Sciences, China

A immunomodulatory protein RH-p36 was identified in the tick Rhipicephalus haemaphysaloides. The cDNA sequence of RH-p36 is 844 bp, and it encodes a deduced 218 amino acid protein with a size of 24 kDa. Bioinformatic analysis shows that RH-p36 is high homology to the immunomodulatory protein p36 of tick Dermacentor andersoni. The recombinant protein expressed in insect cell sf9 suppressed T-lymphocyte mitogen-driven in vitro proliferation of splenocytes as well as the expression levels of several cytokines such as IL-2, IL-12 and TNF-α. Furthermore, the proliferative response of splenocytes isolated from rRH-p36-inoculated mice was significantly lower than for those from control mice, suggesting that rRH-p36 could also directly suppress immune responses in vivo. Interestingly, microarray analysis of the splenocytes showed that the expression of several immunomodulating genes was down-regulated by rRH-p36 inoculation. Disruption of the RH-p36 gene with RNAi led to a 42.5% decrease in the tick attachment rate 24 hours after introduction in the rabbit ears and a 47.5% decrease in the engorgement rate of ticks. Unexpectedly, the RNAi also led to significant effects on tick oviposition. These effects of RH-p36 on blood feeding and ovipisition were further confirmed by vaccine tests using the recombinant protein. These results indicate that RH-p36 is a novel member of immunosuppressant protein involved in tick blood feeding and ovipisition.

Ticks are obligate hematophagous parasites, utilizing blood from their hosts for survival and reproduction. Ticks require large amount of blood, exposing them to great amount of free iron. Iron is both essential and toxic for living organisms. Hemoglobin and ferric-transferrin in vertebrate host blood are the two major iron sources for ticks. Different organisms have several mechanisms for iron metabolism. Among the many aspects of iron biology, two abundant proteins involved in iron transport and storage, ferritin and transferrin (TF). Ferritins are found in prokaryotes, plants and animals, and are characterized by high capacity for iron storage; TF is found in multicellular animals and is characterized with high affinity for iron binding. In ticks, however, iron metabolism remains to be unclear. Here, we analyzed that movement of intracellular ferritin (FER1), secreted ferritin (FER2), and TF obtained from host blood in the hard tick, Haemaphysalis longicornis. Through western blot and indirect immunofluorescent analysis using specific anti-ferritin mouse sera, a similar pattern of expression in different organs and developmental stages was observed for both ferritins. However, only FER2 was detected in the egg and hemolymph. Although intact TF was detected thorough depvelopmental stages, TF was detected in the midguts, hemolymph, and ovaries at tick tissues of adult stage after engorgement. These results indicate that these proteins play a critical role in meal iron transport and iron storage in eggs in Haemaphysalis longicornis.

The role of autophagy in the hard tick *Haemaphysalis longicornis*

Rika Umemiya-Shirafuji[1], Remil Linggatong Galay[2], Hiroki Maeda[3], Hiroyuki Konno[4], Tetsuya Tanaka[5], Kozo Fujisaki[6]
[1]Kagoshima University, Japan, [2]Kagoshima University, Japan, [3]Kagoshima University, Japan, [4]Kagoshima University, Japan, [5]Kagoshima University, Japan, [6]Kagoshima University, Japan

The life cycle of ticks is characterized by alternate off-host and on-host conditions. The generation time is estimated at several years and most ticks spend more than 95% of their life off the host. To understand how ticks obtain energy over a long period of nonfeeding (starvation), we focused on autophagy, a crucial proteolysis system via the lysosomes for various cellular processes that is induced during starvation in eukaryotes. To date, we have isolated 5 homologues of autophagy-related (ATG) genes (ATG3, ATG4, ATG6, ATG8 and ATG12) from the 3-host tick Haemaphysalis longicornis. We have also found autophagic organelles in digestive cells of the midgut of unfed female ticks. In the present study, to determine the relative transcription levels of HlATG genes, real-time PCR was performed using specific primers. The expression levels of each HlATG gene were higher at the egg stage compared with all active stages (larval, nymphal, and adult stages). At nymphal to adult stages, the expressions of HlATG genes were elevated at the premolting stage (during metamorphosis). These results suggest that HlATG genes may function at nonfeeding periods such as the egg stage and metamorphosis. RNA interference (RNAi)-mediated gene silencing of HlATGs are in progress to analyze the function of HlATG genes at nonfeeding periods of the tick. On the basis of these results, the role of autophagy in the tick will be discussed.

Genes and models to understand dispersal: What do they tell us about the current and potential invasive route of the tomato red mite, *Tetranychus evansi*?

Maria Navajas
Institut National de la Recherche Agronomique, France

Dispersal is an important parameter to help understanding species evolution and adaptation. In the case of crop pest, knowing current dispersion pathways and also predict its potential geographical distribution, is particularly useful for species with strong invasion abilities. However dispersion often escapes direct observation in natural populations of small organisms. Population genetics theory predicts that variations of neutral allele frequencies in space can provide a reliable indirect measure of the amount of genetic exchange, and thus of migration of individuals inside a species. Based on examples in spider mites, I will review several features (residence status, natural vs. agricultural, host range, etc) having an influence on population genetic structure. I will then focus on an invasive spider mite, Tetranychus evansi. Native of South America, the mite has emerged as a new destructive pest of solanaceous crops worldwide. Using recent developments in Approximate Bayesian Computation (ABC) and variation in multi-locus genetic markers, the complex historical demography of this cryptic invasive pest could be reconstructed. By distinguishing among multiple pathways and timing of introductions, ABC methods provide insights into complex invasion scenarios and understand pass dispersion pathways. In addition, model distributions informs on the future potential range of the invasive mite, one of the key steps to prevent further spread.

Worldwide journey of invasive alien mites and ticks

Koichi Goka[1], Kimiko Okabe[2], Ai Takano[3]

[1]National Institute for Environmental Studies, Japan, [2]Forestry and Forest Products Research Institute, Japan, [3]National Institute of Infectious Diseases, Japan

Japan is a great economic and depending greatly on importation of natural resources from abroad. So, Japan has always a high risk of biological invasion. Of course, Japan has quarantine systems against alien species adverse to ecosystems, agricultures, forestry, fisheries and human health. However, the invasion risks of alien species continue rising rapidly accompanied by economy globalization. Mite invasion also cannot be an exception. Alien species adverse to natural ecosystems are regulated by the Alien Species Act in Japan. But the law focuses only on visibly recognizable species, so that species too small to see such as virus, bacteria, fungus and mites are beyond of the scope of this law. Alien pests harmful to agricultural crops, including mites, have been severely restricted to be introduced into Japan by the Plant Protection. But recently, the pressure of global trade liberalization has made the law to release of regulations of various pests including spider mites. Infectious diseases and their career species are quarantined by Rabies Prevention Law, Domestic Animal Infectious Diseases Control Law and Human Infectious Diseases Control Law. But these laws cannot cover the wild life diseases. Most serious problem is that wild reptiles which can be careers of ticks and tick borne diseases can be introduced freely. These loopholes of Japan's regulation systems have actually caused mite and tick invasions, which will result in serious problems for mite diversity as well as human society.

Population structure of phytoseiid mite *Neoseiulus womersleyi* and its perspective on conservation biological control

Norihide Hinomoto
NARO-NARC, Japan

In conservation biological control reducing pesticide sprays, preservation of natural enemies by habitat management is thought to enhance their activity. However, it is essential to elucidate the population genetic structure of natural enemies to better conserve them. Here, some topics on the predatory mite Neoseiulus womersleyi (Acari: Phytoseiidae) will be introduced and discussed. N. womersleyi is an important predator of the Kanzawa spider mite, Tetranychus kanzawaki, in tea fields. To conserve them by banker plant systems, population structure of N. womersleyi in a tea field was analyzed by using microsatellite DNA markers. The kinship coefficients between individuals did not differ significantly within a site, but the coefficients gradually decreased with increasing distance. Therefore, the management unit for conservation of N. womersleyi should be this approximate scale. In commercially grown chrysanthemums are well protected from lepidopteran pests by net barriers; however, some small insects and mites have developed resistance against chemical sprays. Here, we used DNA markers to identify the species of phytoseiid mites around the chrysanthemum fields. The dominant phytoseiid mite was N. womersleyi, which accounted for more than 70% of those trapped and identified. Next, their population structure was analyzed using microsatellite markers. Spatial autocorrelation indices were low at all distance ranges, indicating that a high level of gene flow occurred across this area. It is possible that frequent mowing of the area around the fields might enhance dispersal of the phytoseiid mites, and thereby account for the observed population structure of the species.

Patch-leaving decision of the predatory mite based on multiple signals

Taro Maeda
National Institute of Agrobiological Sciences, Japan

How to find a prey patch and how long to stay there are two major factors determining the foraging efficiency of predators and parasitoids. Many predators and parasitoids use herbivore-induced plant volatiles as cues for their foraging behaviors in many systems consisting of plants, herbivores, and natural enemies. For example, the predatory mite Neoseiulus womersleyi, which is a specialist predator of tetranychid mites, is attracted to volatiles emitted from plants infested with their prey. Once predators have located a prey patch, multiple pieces of information are available to decide their residence time in the patch. Contact chemicals associated with prey and competitors, and volatiles from plants would exhibit the condition of the currently inhabiting patch. The volatile chemicals from outside the patch are important information to evaluate the surrounding area. The resource level in habitat can be estimated by foraging experience of predators. Our experiments using small leaf disks showed that the residence time of N. womersleyi was short when prey-related products such as exuviae, feces and webbing were on a prey patch. The residence times of predatory mites was affected by the presence of HIPV from outside the patch and previous foraging experiences. N. womersleyi appears to determine residence time in the current patch based on the resource level in the current patch and that in the surrounding habitat.

Local movement of prey-predatory mites and implementation in management

Chuleui Jung[1], Siyong Kim[2], Joon Ho Lee[3]

[1]Andong National University, Republic of Korea, [2]Dongbu hannong, Republic of Korea, [3]Seoul National University, Republic of Korea

Two spotted spider mite and European red mite are the important pests in apple and pear in Korea. In fruit tree system, twospotted spider mite moves more frequently and widely than European red mite. Neoseiulus womersleyi is the dominant among spider mite predator guild. We have studied the movement pattern of Tetranychus urticae and N. womersleyi within tree, between tree, within orchard, and even among orchards and surrounding. Overwintered adult T. urticae moved from the tree trunk to the ground vegetation mostly from late March to mid April with a daily peak activity from noon to 4 p.m. Movement of overwintered N. womersleyi from the tree trunk to ground was negligible, mostly because of the different overwintering habitat. Movement of T. urticae from the ground vegetation to apple tree began from mid May and that of N. womersleyi followed in two weeks. When the densities of T. urticae and N. womersleyi were high in the tree canopy, dispersal movements of both species occurred by downward ambulation or aerial take-off. In aerial movement, distance of the dispersal ranged less than 100 m with exponential decay pattern. However, significantly longer transportation events were also noticed, but not experimentally validated. Summarizing, we present options for better mite management tactics.

Belowground fungus adaptively modulates the foraging behavior of an aboveground plant-inhabiting predator

Peter Schausberger[1], Stefan Peneder[2], Daniela Hoffmann[3]
[1]*University of Natural Resources and Life Sciences, Austria,* [2]*University of Natural Resources and Life Sciences, Austria,* [3]*University of Natural Resources and Life Sciences, Austria*

Arbuscular mycorrhiza, the association between mycorrhizal fungi and plant roots, is a ubiquitous phenomenon but whether and how mycorrhiza affects aboveground herbivore-carnivore interactions is largely unknown. On bean plants Phaseolus vulgaris, the mycorrhizal fungus Glomus mosseae enhances the fitness of the herbivorous two-spotted spider mite Tetranychus urticae and its natural enemy, the predatory mite Phytoseiulus persimilis, via changes in host plant and prey quality, respectively. Thereupon, we hypothesized that foraging P. persimilis are able to recognize mycorrhiza-enhanced prey quality directly via prey-related cues and indirectly via herbivore-induced plant volatiles (HIPV). We assessed the response of foraging P. persimilis to direct and indirect cues using choice cages and a Y-tube olfactometer, respectively. P. persimilis used direct prey-related cues, mainly derived from eggs, to discern prey quality and preferentially resided and oviposited close to prey fed on mycorrhizal plants. P. persimilis responded strongly to HIPVs emitted by plants infested for six days and preferred HIPVs of mycorrhizal plants to those of non-mycorrhizal plants. In contrast, the predators were little responsive and indiscriminative regarding mycorrhization when exposed to volatiles emitted by non-infested plants. Analysis of the HIPV composition by proton-transfer-reaction mass spectrometry (PTR-MS) revealed that mycorrhiza increased the emission of β-ocimene and β-caryophyllene, two compounds synthesized de novo upon spider mite attack. Our study shows that plant-inhabiting carnivores may recognize mycorrhiza-induced changes in the quality of herbivores as prey via both direct and indirect cues, and provides a key example of an adaptive indirect interaction between a belowground microorganism and an aboveground predator.

Aerial dispersal of *Aceria carvi* (Acari: Eriophyidae)

Rostislav Zemek[1], Frantisek Reindl[2]
[1]*Biology Centre AS CR, Czech Republic,* [2]*Biology Centre AS CR, Czech Republic*

Aceria carvi Nal. is a serious pest of biennial caraway (Carum carvi L.) in Europe. The mite attacks plant tissues and causes development of flower galls which produce no seeds thus reducing yield substantially. It was presumed that the pest relies on dispersal by wind currents for transfer from the field of senescent plants to the field of young plants during summer. Airborne dispersal of A. carvi was recorded by trapping mites in petroleum jelly on microscope slides mounted vertically on wood stick 1.5 m above ground level. The effect of wind speed on mite behavior was studied under laboratory conditions using a specially made wind tunnel allowing microscopic observation. The results revealed that number of mites caught on sticky traps increased in time till about four weeks before the caraway harvest. A positive correlation between A. carvi density on caraway umbels and number of airborne mites was found. Wind-tunnel experiments showed that adult females actively entered the air current at speed > 0.5 m/s by orienting their bodies and using the caudal lobe as a springing mechanism. The greater the wind speed, the sooner the mites were carried aloft.

Epidemiology of ticks (Acari: Ixodidae) infesting buffaloes (*Bos Bubalus bubalis*) in district Toba Tek Singh, Punjab, Pakistan

Muhammad Sohail Sajid[1], Asif Iqbal[2], Muhammad Nisar Khan[3], Muhammad Kasib Khan[4], Zafar Iqbal[5]

[1]University of Agriculture, Faisalabad-38040, Pakistan, Pakistan, [2]University of Agriculture, Pakistan, [3]University of Agriculture, Faisalabad, Pakistan, Pakistan, [4]Huazhong Agricultural University, China, [5]University of Agriculture, Pakistan

The current research was conducted in order to study the epidemiological parameters on the prevalence of tick infestation and associated risk factors in buffaloes of district Toba Tek Singh of central Punjab, Pakistan. The prevalence of ticks in buffaloes was recorded as 31.21% (352/1128). Among various species of ticks, the prevalence of Hyalomma marginatum (20.12%) was higher ($P<0.05$; OR= 1.75) as compared with Rhipicephalus microplus (11.08%). Various catagories of age, sex and breed of the host were found equally susceptible ($P>0.05$) to ticks. In different observed management and husbandry practices, the prevalence of ticks was found higher in animals kept on un-cemented floor (15.51%; OR= 2.17) followed in order by partially cemented (9.39%; OR=1.29) and cemented floor (6.29%; 71/1128) while feeding system, housing system and animal keeping were not found associated with the prevalence of ticks ($P>0.05$). Variation in infestation of ticks at different body parts including the head, neck, ear, dewlap, back, abdomen, foreleg, shoulder, hind leg, congenital areas and the tail was recorded which were ranges from highest at inside thigh (17%) to lowest at rump. In the present survey, highest prevalence was recorded in July and lowest in December. Comparison of hematological changes shows remarkable differences between infested and non-infested animals, in the form of low values of infested animals whereas an increment in biochemical parameters values has been observed in tick infested animals. The results of the present study may implicit significant data for the for better planning tick control program in the study area.

Rickettsiae that parasitize ticks and mites

Allen L Richards
Naval Medical Research Center, U.S.A.

Rickettsiae are obligate intracellular bacteria that require eukaryotic cells to serve as their host in order to grow. Rickettsiae have historically been placed into three groups based upon serologic and genotypic typing: the typhus group (TG) including Rickettsia prowazekii and Rickettsia typhi; scrub typhus group (STG) including Orientia tsutsugamushi and Orientia chuto; and the larger more diverse spotted fever group (SFG) that comprises over 20 species including the well known pathogens Rickettsia rickettsii, Rickettsia conorii, Rickettsia japonica, Rickettsia africae, etc. While not all rickettsiae have been proven to be pathogenic the list of formally non-pathogenic rickettsiae added to the pathogenic roles has increased over the last several years. In fact, approximately 15 additional tick-borne rickettsioses have been described within the last 20 years alone. This brief review will discuss emerging and reemerging pathogenic and non-pathogenic rickettsiae found in ticks and mites.

Scrub typhus caused by Orientia tsutsugamushi is an endemic disease in Korea. Chigger mites and field rodents play roles in transmission of the diseases the vector and host of the agent. The purpose of this study is to investigate the density of the chigger mites and field rodents, identification of them and infectivity of the mites with Orientia in Korea. We captured field rodents and collected mites from them between April and November 2009 in fifteen localities in Korean. We captured a number of 78 mice in the central and 62 mice in the southern region and Apodemus agrarius was dominant species in both regions. A total of 9,232 mites were collected from the mice and identified. PCR and sequencing analysis showed that 35 (11.3%) out of the 309 L. scutellare were infected with O. tsutsugamushi, 52 (9.5%) out of the 548 L. pallidum, 8 (11.4%) of the 70 L. orientale, 2 (11.8%) of the 17 E. koreaensis, and 1 (1.1%) of the L. palpale were infected. Phylogenetic analysis showed that strain were Boryong [dominant strain; total number of mites tested (n=1,136); number of positive mites (n=77), 6.8%], Kanda (n=4, 0.4%), Oishi (n=3, 0.3%), Jecheon (n=1, 0.1%), Youngworl (n=1, 0.1%), Wonju (n=1, 0.1%), and not determined (n=17, 1.4%). The density of mites was high at a dry field or a farm and the O. tsutsugamushi infection rate of the mites was high at the site near by a storing reservoir.

Tick-borne pathogen surveillance in the country of Georgia: Implications for unrecognized spotted fever group rickettsial disease in humans.

John Scott Lee[1], Lewis Long[2], Sarah Pisarcik[3], Elizabeth Wallace[4], Monica O'Guinn[5], Nikoloz Tsertsvadze[6], Irakli Sikharulidze[7], Nikoloz Kiria[8], Mariam Zakalashvili[9], Maka Kokhreidze[10]

[1]United States Army Medical Research Institute of infectious Diseases, U.S.A., [2]Walter Reed Army Institute of Research, U.S.A., [3]USAMRIID, U.S.A., [4]Naval Medical Research Center, U.S.A., [5]US Army Medical Research and Materiel Command, U.S.A., [6]National Center for Disease Control, Georgia, [7]National Center for Disease Control, Georgia, [8]National Center for Disease Control, Georgia, [9]National Center for Disease Control, Georgia, [10]Laboratory of the Ministry of Agriculture, Georgia

As part of the Defense Threat Reduction Agency's Cooperative Biological Engagement Program, tick-borne pathogen surveillance and diagnostic training was conducted in the country of Georgia. Ticks were collected using tick drags/flags and from domestic and peridomestic animals during the spring (May-June) and fall (September) seasons. From 2008 to the present, 4,411 ticks were collected and sorted by species and location into 1,236 pools. The pools were screened using real-time PCR assays designed to detect the genus Rickettsia or to detect spotted fever group (SFG) rickettsia. To confirm the identity of the Rickettsia present in the positive pools, multi-locus sequence anaylsis of the ompA, ompB and sca4 genes was completed and confirmed the presence of Rickettsia slovaca, R. raoultii, and R. aeschlimannii. These three species of Rickettsia have been associated with tick-borne lymphadenopathy (also called Dermacentor-borne necrosis erythema lymphadenopathy) disease in humans that ranges from eschar at the tick bite site and associated regional lymphadenopathy, to fever, headache, and rash. Two of these species, R. slovaca and R. aeschlimannii, are known to be transovarially and transstadially transmitted (unknown for R. raoultii) and have been isolated from Dermacentor species and Hyalomma species ticks, respectively, and R. raoultii has been isolated more frequently from D. marginatus and D. reticulatus ticks than R. slovaca. Geographical distributions of the tick species collected in Georgia and their association with SFG rickettsial pathogens will be presented.

Australian ticks, their rickettsial symbionts and associated human diseases

Gemma Vincent[1], John Stenos[2], Mohammad Yazid Abdad[3], Leonard Izzard[4], Aminul Islam[5], Stephen Graves[6]

[1]Australian Rickettsial Reference Laboratory, Australia, [2]Australian Rickettsial Reference Laboratory, Australia, [3]Australian Rickettsial Reference Laboratory, Australia, [4]Australian Rickettsial Reference Laboratory, Australia, [5]Australian Rickettsial Reference Laboratory, Australia, [6]Australian Rickettsial Reference Laboratory, Australia

Throughout Australia, a number of rickettsiae have been identified within a variety of tick species. The hard ticks Ixodes holocyclus and I. tasmani, which are distributed along the eastern seaboard of the country, have been shown to harbour Rickettsia australis. Recently, we have demonstrated that I. tasmani ticks in Tasmania are carriers of a novel agent, Candidatus R. tasmanensis. In south-eastern Australia, Bothriocroton [Aponomma] hydrosauri, the vector for R. honei, is widely distributed. A subspecies of R. honei (strain marmionii) has been identified in a different tick species, Haemaphysalis novaguineae, found in the north of the country. In Western Australia two tick species, Amblyomma triguttatum and I. antechini, have been shown to harbour the newly identified rickettsial agents Candidatus R. gravesii and Candidatus R. antechini respectively. The soft bodied tick, Argus dewae has also been shown to carry a novel agent, Candidatus R. argusii. This tick has been identified in Victoria and Tasmania but its geographical distribution could be significantly greater. Although we have elucidated several rickettsial species within both soft and hard bodied ticks in Australia, characterisation of these agents is still in its infancy. Human disease has only been associated with three of the species described, namely R. honei and R. honei subspecies marmionii which both cause Flinders Island spotted fever, and R. australis which is responsible for Queensland tick typhus. Further research will allow us to determine the pathogenicity of the Australian rickettsiae and the true association of these agents with human disease.

Ecological changes affecting the distribution and potential for tick-borne diseases in the Republic of Korea

Terry Allen Klein[1], Heung-Chul Kim[2], Won-Jang Jang[3], Kyung-Hee Park[4], Joon-Seok Chae[5], Baek-Jun Kim[6], Richard Robbins[7], Allen Richards[8]

[1]Public Health Command Region-Pacific, U.S.A., [2]65th Medical Brigade, Republic of Korea, [3]Konkuk University, Republic of Korea, [4]Konkuk University, Republic of Korea, [5]Seoul National University, Republic of Korea, [6]Seoul National University, Republic of Korea, [7]Armed Forces Pest Management Board, U.S.A., [8]Naval Medical Research Center, U.S.A.

Over the past century the Korean landscape changed as a result of Japanese occupation, three major wars, and most recently, economic recovery. At the end of the Korean War (1953), the hills and mountains were nearly treeless. A tree planting policy instituted in the 1960s reestablished long-ago lavish forested mountains and hills that make up >70% of the South Korean landscape. Today, these same barren mountains and hills, now covered with 10-50 year-old forests, provide harborage for wild animals, including deer and wild pigs, and birds, increasing the potential for ticks and associated zoonotic pathogens. As tick-borne diseases are not reportable, the impact on civilian and military populations is unknown. However, a recent post-deployment investigation of nearly 9,000 US soldiers deployed to Korea in 1995 showed that approximately 2% seroconverted to SFG Rickettsia, while only 0.2% seroconverted to scrub typhus. In collaboration with Seoul National University and Konkuk University, the office of Force Health Protection and Preventive Medicine, 65th Medical Brigade, has conducted tick-borne disease surveillance (small-large mammals and tick drags/flags) since 2001. Primary ticks collected from small mammals were Ixodes nipponensis, while Haemaphysalis longicornis, H. flava, H. phasiana, and I. pomerantzevi were the primary ticks collected by tick drag. This surveillance resulted in two new records of ticks and the identification of tick-borne encephalitis, Rickettsia, Ehrlichia, Anaplasma, and Bartonella spp. and Borellia burgdorferi.

Ovarian stage and vitellogenin gene expression in diapause adults of the two-spotted spider mite *Tetranychus urticae*

Hideharu Numata[1], Yuko Kawakami[2], Shin G. Goto[3], Katsura Ito[4]
[1]Kyoto University, Japan, [2]Osaka City University, Japan, [3]Osaka City University, Japan, [4]Kochi University, Japan

The most conspicuous aspect of diapause in adult female insects is the discontinuation of oogenesis. In diapause adults, the synthesis of vitellogenin and its mRNA expression are suppressed. However, only a few physiological and molecular studies have been performed on the adult diapause in mites. In the present study, first we histologically observed the ovaries of the diapause females of the two-spotted spider mite Tetranychus urticae and compared them with those of the nondiapause ones. In nondiapause females, transparent oocytes became opaque with yolk deposition between days 0 and 1 in the adult stage at 20ºC. In diapause females, however, ovarian development ceased at a stage having transparent oocytes without yolk deposition; this stage corresponded to the day-0 stage of the nondiapause females. Then we characterized the vitellogenin genes and examined their expression pattern in the diapause and nondiapause females by northern blot analysis. The diapause females did not express vitellogenin mRNA, and therefore, vitellogenesis was indicated to be regulated at the transcriptional level in diapause.

Overwintering ecology of phytoseiid mites in fruit orchards

Chuleui Jung[1], Mitsuhiro Kawashima[2], Hasan El Taj[3], Joon-Ho Lee[4]
[1]Andong National University, Republic of Korea, [2]Dow AgroSciences, Japan, [3]Hajee Mohammad Danesh Science and Technology University, [4]Seoul National University, Republic of Korea

In Korea, two species of phytoseiidae are important in the fruit orcahrd mite biological control; Neoseiulus womersleyi and N. californicus. Two species differ in overwintering strategies and also the feeding specialization. The former is a diapausing and the latter is not. From the series of field studies, we developed a method to conserve the phytoseiid population for better conservation biological control by provisioning the sheltered habitat. In this case, providing the food items such as Tetranychus urticae enhanced the field survival of phytoseiids.

Is solar ultraviolet-B radiation an ultimate factor causing diapause in *Tetranychus urticae* under temperate climatic conditions?

Masahiro Osakabe[1], Shoko Kawaguchi[2], Yasumasa Murata[3]
[1]*Kyoto University, Japan,* [2]*Kyoto University, Japan,* [3]*Kyoto University, Japan*

Diapause in females of Tetranychus urticae is induced by short day length and low temperature, representing the overwintering stage. Previous studies revealed reinforcement of cold hardiness in red diapausing females. However, green non-diapausing females also successfully overwinter on the field host plants in temperate central Japan, suggesting that freezing (or cold) is not evolutional force for diapause induction in such region. Several alternative hypotheses concerning evolutional significance of diapause attributes in arthropods have been suggested, e.g., to control the timing of reproduction, and to survive starvation. Biological impact of solar ultraviolet-B (UVB) radiation on T. urticae has been well documented, and it is probably a major factor for the mites to inhabit lower leaf surfaces. Red diapausing females are known to be invulnerable to UVB radiation in comparison with green non-diapausing females. We studied seasonal change in the deleterious effects of solar UVB radiation, dose-response, and factors in red pigmentation. As a result, the deleterious effects of solar UVB radiation were the most serious in spring. Extent of the biological impact obeyed the Bunsen-Roscoe's law. Eggs and larvae were more vulnerable than adult females. Of the carotenoids, astaxanthin was particularly accumulated in red diapausing females. Feeding was essential for diapausing females to change their body color; probably caused by the accumulation of astaxanthin. Based on these results, we will discuss about the significance of UVB radiation for this mite to maintain diapausing attributes under temperate climatic conditions.

Virtual reality experiments on a micro-locomotion compensator: seasonal changes in the spectral sensitivity of *Tetranychus urticae*

Takeshi Suzuki[1], Takeshi Kojima[2], Makio Takeda[3], Masayuki Sakuma[4]
[1]Chiba University, Japan, [2]Kyoto University, Japan, [3]Kobe University, Japan, [4]Kyoto University, Japan

Leaves absorb ultraviolet radiation (UV) and visible radiation (VIS), but transmit some of VIS; thus, the undersurface of leaves is less harmful. This may explain the preference of Tetranychus urticae for the undersurface of leaves. To verify this theory, we examined the orientation behavior of T. urticae on a micro-locomotion compensator (MLC). The MLC maintains a freely walking test mite on a glass plate in a constant position by sliding the plate horizontally and logs the positional data in a programmed checkered pattern of light and dark patches. In the light patches, the mite was irradiated with non-directional light by LEDs. Both nondiapausing and diapausing females spent more time in the dark patches than in the UV-lit patches. Nondiapausing females spent more time in the VIS-lit patches than in the dark patches, whereas diapausing females did not show a preference in this regard. Our results show that nondiapausing females avoid UV and are attracted to VIS. These results suggest that nondiapausing females use spatial differences in the distribution of UV and VIS between the two sides of the leaf as a reliable criterion for choosing their habitat. The preference of diapausing females for sunless hibernacula can also be explained on the basis of UV avoidance without any attraction to VIS. Furthermore, the decrease in attraction to VIS accompanying diapause suggests the presence of at least two different photoreceptors each for UV and VIS. We anticipate that this study will provide a basis for examining the seasonal changes in photoreception systems.

Underground ecology of mites in soil porosity and its significance in pest management

Hiroshi Amano
Kyoto University, Japan

Both applied and basic entomologists are prone to watch only arboreal ecosystems of organisms and to overlook the reality of underground world. Although some ecological knowledge was accumulated, a few solutions have been provided. Problems of soil-inhabiting pests including mites may persist and expand especially under the current trend with more organic materials and less chemicals in agriculture. Understandings of underground ecosystem with biotic and abiotic interactions are urgently needed to establish a sustainable measure of pest management. In the present review paper, the greenhouse spinach mite, Tyrophagus similis, is taken as a model case and current problems and strategic approaches in progress in Japan will be demonstrated to contribute to the development of future pest management. Country-wide distribution of greenhouse spinach damage by mites became evident since the 1990's and a recent increase in use of organic materials and fertilizers (under the government guiding principle) may have promoted further damages. Farmers are facing a difficult task without much support from scientific sectors. An integrated project started in 2010 under a support of Japanese government and scientific approaches were directed form views of biological, chemical, physiological and cultural managements of mites. It is now on the way of establishing a basis of the integrated management system, starting form pest forecasting (by invention of a new watchman trap) to a sustainable control (by biotic and abiotic management of soil environments) of mites in the Black Box.

Identification of the female sex pheromone and unique fatty acid metabolisms of *Tyrophagus similis* (Acari: Acaridae).

Naoki Mori[1], Takako Aboshi[2]

[1]Kyoto University, Japan, [2]Kyoto University, Japan

Tyrophagus similis (hourensou kenaga-konadani in Japanese) is a pest species in horticulture, causing serious damage to spinach, melon, cucumber, pumpkin and maize in green houses and fields (Nakao and Kurosa, 1988). This species reproduces via mating between males and females, and mating pairs are incessantly observable in the stock culture, strongly suggesting the presence of a female sex pheromone in this species. Here, we report a bioassay driven isolation of a female sex pheromone in T. similis, identified as S-(+)-isopiperitenone [(S)-3-methyl-6-isopropenyl-2-cyclohexen-1-one], previously identified as the alarm pheromone of the mite (Kuwahara et al., 1987; Maruno et al., 2012). A number of insect species are able to produce linoleic acid, a fatty acid that was previously believed to be essential for all animals. Here, we investigated unique metabolism of polyunsaturated fatty acids, precursors of prostaglandins and other eicosanoids, in T. smilis.

Reproductive capacity of greenhouse spinach mite, *Tyrophagus similis* Volgin, feeding on commonly used organic fertilizers

Muhammad Naveed Baloch[1], Naoki Mori[2], Takako Aboshi[3], Hiroshi Amano[4]
[1]Kyoto University, Japan, [2]Kyoto University, Japan, [3]Kyoto University, Japan, [4]Kyoto University, Japan

Greenhouse spinach mite Tyrophagus similis inhabits soil under 5 cm depth. In soil it mainly feeds on organic fertilizers, plant debris fungus, nematodes and microorganisms. For its control, knowledge of its food resources is important. A series of experiments was conducted to investigate reproductive performance of mites while feeding on organic fertilizers in the laboratory conditions. Four fertilizers (Fish lees, Poultry manure, Rapeseed oil cake and Agret©) were provided as fresh food to mites. Nutritional value of fertilizers was observed by means of fecundity of mites for first five days. The results showed that fish lees have higher nutritional value. To know components of each fertilizer responsible for higher fecundity, an addition of amino acids and a variety of fatty acids (saturated and unsaturated) was investigated. The results showed no significant difference of fecundity recorded on coated and uncoated fertilizers with amino acids. In case of addition of fatty acids, the results showed that oleic acid was high, linoleic and stearic acids were moderate, palmitic and linolenic acids were low nutritional values. The promoting or repellent properties were studied by coating extracts of fertilizers on each other. The results showed that no particular repellent effects were found, while fish lees extract has a high promoting effect. To examine nutritional value of fertilizers after used in the field, they were stored for one and three weeks in spinach greenhouse soil and they were provided to mites. The results showed that nutritional value of fertilizers sharply decreased when stored in soil.

Hydrozetid mites (Oribatida: Hydrozetidae) on water plants in Lake Biwa, Japan, with some notes on its biogeography

Satoshi Shimano[1], Takuya Sato[2], Gen-ichi Kuriki[3], Yasushi Kusuoka[4]

[1]Miyagi university of education, Japan, [2]Miyagi university of education, Japan, [3]Ohu University, Japan, [4]Lake Biwa Museum, Japan

The Hydrozetid mites are usually recorded in Sphagnum bogs in Japan. We investigated an ancient freshwater lake, the 4-million-year-old Lake Biwa in Japan. Hydrozetes parisiensis Grandjean, 1948 was collected from submerged several species of macrophytes by shipboard sampling on two occasions (15th November 2008) in the South Basin of the lake. On this first occasion, at a site six meters deep, the mites occurred within one meter of the water surface. On the second occasion, they were found at several additional sampling points (25th-27th February 2010). This species has previously been known from Europe. In this report, additionally we present the record of H. parisiensis from Lake Biwa and several places in Japan, and together with a clarification of some aspects of its morphology and the sequence of its D3 region of 28S rDNA.

Keywords:*Hydrozetidae, Oribatida, freshwater lake, locality record, Japan, D3 region of 28S rDNA*

Designing digital multi-media identification tools for invasive mites

Terrence W. Walters[1], Ronald Ochoa[2], Jennifer Beard[3]

[1]United States Department of Agriculture, U.S.A., [2]United States Department of Agriculture, U.S.A., [3]University of Maryland and Queensland Museum, U.S.A.

Developing and delivering identification aids, keys, and tools to support pest identification requires an important investment in the planning and design phases of a resource to ensure they are valued and used by end-users. Agencies involved with plant protection and quarantine typically have personnel off-shore, at ports, and domestically involved with survey, detection, trade, and identification that require rather diverse types of support based upon levels of expertise and responsibilities. Resource developers should take into consideration the following during the planning and design phases for a future resource: 1) how will the end-user access the resource, 2) what is the level of expertise (i.e., taxonomy, IT, etc.) of the end-users, 3) what type of resource is required for the responsibility (e.g., screening aids, keys, fact sheets, portal, etc.), 4) how and where will the resource will be used (i.e., field, laboratory, identification, verification, diagnostics, surveys, mobile devices, etc.), 5) what type of results are expected by the use of the resource, and 6) what is the scope (i.e., breadth, circumscription) of the resource. Based on numerous years developing and delivering specialized digital multi-media resources for a diversity of teams associated with the United States Department of Agriculture (USDA), the authors will present guidelines for planning and designing valuable, user-friendly, identification resources to support mite identification.

Reproductive performance and acaricide susceptibility of the invading tomato red spider mite, *Tetranychus evansi* Baker & Pritchard

Tetsuo Gotoh
Ibaraki University, Japan

The tomato red spider mite, Tetranychus evansi, is an invasive herbivore specialized on solanaceous plants, which rapidly spread throughout the world during the last decade. It causes serious damage to crops in Africa and Europe, but has not yet been reported to damage crops in Japan, where it was first found in 2001. To evaluate the potential threat of Tetranychus evansi, life-history parameters, such as rate of development and intrinsic rate of natural increase (rm), for mites collected on seven sites worldwide were assessed on Solanum nigrum. For egg-to-adult development, the lower thermal thresholds (t0) were 11.6-12.0°C and the thermal constants (k) 127-142 degree-days. The rm-values increased with temperature increasing from 15 to 35°C. At 25°C, rm ranged from 0.265 to 0.277 which is high among Tetranychus species. These results indicate that T. evansi has the potential to become a serious pest on solanaceous crops in Japan, just as it has become in Africa and Europe. This study also determined the susceptibility of adults and eggs of nine strains of T. evansi (the seven mentioned earlier plus two more Japanese strains) to 11 acaricides, because chemicals are used as the first line of control when a new pest arises. For all but one acaricides the LC50's on all nine strains were much lower than the recommended concentrations, suggesting they could be used to control T. evansi, should it occur in high numbers in crops.

Tomato red spider mite, *Tetranychus evansi* Baker&Pritchard: Invasionand management in Africa

Komi K. M. Fiaboe[1], Markus Knapp[2], Gilberto J. De Moraes[3], Imelda P. Furtado[4]

[1]ICIPE, Kenya, [2]Koppert Biological Systems, Netherlands, [3]ESALQ-Universidade de Sao Paulo, Brazil, [4]CCBS, Universidade Regional do Cariri, Brazil

The tomato red spider mite, Tetranychus evansi, is the most important dry season pest in tomato and indigenous Solanaceae vegetable (nightshades) production in various African countries. The pest probably originates from southern America and spread to Africa, Europe and Asia. It however represents a serious problem mainly in Africa. Several predatory mite species successfully used against other Tetranychus spp. were tested against T. evansi on solanaceous plants, but the results were not promising. However, when T. evansi was reared on plants outside the Solanaceae family, predatory mites like N. californicus were found promising. The pest is believed to sequester toxic compounds from solanaceous plants to defend itself against predators. To control this pest, small scale farmers in Africa rely exclusively on synthetic pesticides, particularly dicofol, dimethoate and lambda-cyhalothrin. However, T. evansi quickly developed resistance against these products. Plant resistance to T. evansi was found in some tomato hybrids and nightshade species. The pest is able to suppress induced plant defense mechanisms. Surveys in parts of South America identified as priority areas by a climatic model, revealed Phytoseiulus longipes (Phytoseiidae), Stethorus tridens (Coccinellidae) and Neozigytes floridana (Entomophthorales) as the most promising biocontrol agents. Phytoseiulus longipes was introduced to Kenya in 2005. A pilot release in 2007 resulted in establishment, although further releases are considered necessary for successful control of the pest. In addition to the natural enemies found in South America, Metarhizium anisopliae ICIPE78 was identified in Kenya as very effective against T. evansi and it is now patented for commercialization.

Expansion and occurrence of *Neoseiulus californicus* (McGregor), a prospective predacious mite species, in Japan and Korea, and the conservation for biological control of spider mites

Hidenari Kishimoto[1], Mitsuhiro Kawashima[2], Chuleui Jung[3], Hiroshi Amano[4]

[1]NARO Institute of Fruit Tree Science, Japan, [2]Dow AgroSciences, Japan, [3]Andong National University, Republic of Korea, [4]Kyoto University, Japan

Neoseiulus californicus is an effective predator species of spider mites, and has worldwide distribution, including Europe, Africa, and North and South Americas. It had been a minor species in East Asia before the 1980s; however, in Japan, both the abundance and geographical distribution of N. californicus have sharply increased in and after the 1990s. This species was first found in central Japan, but has recently expanded its distribution to the southwest and southern areas. In Korea, the occurrence of N. californicus in the field was first reported in the southernmost island, Jeju Island, in the 2000s. Within the short period, N. californicus has become a dominant species in many fruit orchards with conventional control, such as Japanese pear and citrus. In addition, N. californicus has rapidly replaced the position of Neoseiulus womersleyi, which previously occupied a dominant position among phytoseiid fauna. Thus, N. californicus is considered a new prospective predator species against spider mites in these areas, although the reasons for the increase and expansion remain unclear. As N. californicus populations in East Asia have no diapause capacities, surveys on overwintering sites of this species is important to establish the biological control strategy on perennial crops, such as fruit trees. Most N. californicus overwintered on herbaceous plants with rosette-type leaves on the ground. N. californicus also utilized artificial shelters, such as urethane foam set on the ground in fruit orchards as overwintering sites. Thus, provision of these overwintering sites may be effective for conserving N. californicus populations in orchards.

Agricultural acarology in the Philippines: Pest mites and their natural enemies

Divina Medina Amalin
BalikScientist Program, Philippines

The mite fauna of the Philippines is certainly a rich one. In agriculture, many species are recorded as host sampling is expanded. A wide range of phytophagous mites are recorded predominant commercial mite pests in Philippine agriculture. Among these phytophagous mites, spider mites under the family Tetranychidae are the most economically important as they are known pests of both agronomic and horticultural crops. Predatory mites acting on these phytophagous mites are also diverse particularly of importance are the phytoseid mites. Efforts to rear the phytoseid mites are made with some degree of success but efforts are primarily focused on methodology rather than for mass rearing and field releases. Augmentation of these predatory mites in the field is confined to conservation and habitat manipulation.

Management of *Varroa destructor*, the ecto-parasitic mite of the honey bee using fungal pathogens

Lambert Kanga[1], Walker Jones[2], John Adamczyk[3], Carlos Gracia[4], John Cascino[5], Muhammad Haseeb[6]
[1]Florida A&M University, U.S.A., [2]USDA-ARS, U.S.A., [3]USDA-ARS, U.S.A., [4]USDA-ARS, U.S.A., [5]Sylvan BioProducts, U.S.A., [6]Florida A&M University, U.S.A

The honey bee, Apis mellifera L., is critical not only for honey production, but also for crop pollination. The added value to U.S. crops from honey bee pollination was estimated at $14.6 billion annually. The ecto-parasitic mite Varroa destructor Anderson and Trueman is currently the most serious pest of honey bee around the world. Bee hives infested with Varroa mite can perish within a few weeks. In addition, Varroa mite has developed resistance to the only two miticides used for control and threatens the honey bee industry and agriculture. Therefore, we examined the use of fungal pathogens as sustainable and environmentally friendly alternative control strategies for Varroa mite. Several fungal isolates were screened for pathogenicity and virulence against Varroa mites. Honey bee colonies with heavy infestations of Varroa mites were treated with different formulations of fungal spores to determine efficacy. Hirsutella thompsonii and Metarhizium anisopliae were found to be highly pathogenic to the mite and harmless to honey bee. Data in the last six years indicated that strip or paddy-blend formulations of M. anisopliae were successful in controlling populations of Varroa mite. We determined that fungal spores (1 x 1010viable spores per gram) with 98% germination and high pathogenicity (95% mite mortality at day 7) provided successful control of mite populations in established honey bee colonies at 10 g of conidia per hive (applied twice). Overall, biological control of Varroa mite is feasible and could be a useful component of an integrated pest management program for the honey bee industry.

[1]The University of Southern Mississippi, U.S.A., [2]The University of Southern Mississippi, U.S.A., [3]The University of Southern Mississippi, U.S.A., [4]Georgia Southern University, U.S.A., [5]The University of Southern Mississippi, U.S.A., [6]Office of the Deputy Under Secretary of Defense for Installations and Environment, U.S.A., [7]Georgia Southern University, U.S.A., [8]The University of Southern Mississippi, U.S.A.

Birds are capable of carrying ticks and, consequently, tick-transmitted microorganisms over great distances and over geographical barriers such as oceans and deserts. Ticks are hosts for several species of spotted fever group rickettsia (SFGR), which can be transmitted to vertebrates during blood meals. In this study, the prevalence of SFGR was examined in ticks infesting migratory songbirds by using Polymerase Chain Reaction (PCR). During the 2009 and 2010 spring migration season, ?2064 northward-migrating passerine songbirds were examined for ticks at Johnson Bayou, Louisiana. A total of 120 ticks were removed from 38 songbird species for tick species identification and SFGR detection. The ticks were identified as Amblyomma longirostre, Amblyomma nodosum, Amblyomma calcaratum, Amblyomma maculatum, Amblyomma spp. and Haemaphysalis species, all originating from South America by comparing their 12SrDNA gene sequence to homologous sequences in GenBank. The nucleotide sequence similarity of the PCR products revealed several exotic SFGR. Our results indicate that exotic tick species arriving attached to migrating songbirds may play an important epidemiological role in importing previously unknown SFGR to the North America.

Functional morphology of accessory structures involved in reproduction among gamasid mites (Acari, Anactinotrichida)

Antonella Di Palma[1], Gerd Alberti[2]
[1]*University of Foggia, Italy,* [2]*Universitat Greifswald, Germany*

In Mites sperm transfer can be direct or indirect. In direct sperm transfer, males introduce the sperm into the females either via the primary female genital opening (architocospermy and neotocospermy) or via a secondary genital opening (porospermy, podospermy/gonopody, neopodospermy). In indirect sperm transfer, males produce and deposit a spermatophore on the substrate, then, the females collect and transfer it to their genital opening. So contact between the partners is not a prerequisite. Gamasida represent the most species-rich taxon in the anactinotrichid mites and occur world wide. Among gamasid mites only direct sperm transfer occurs but architocopermy, neotocospermy, and neopodospermy have been observed. Several anatomical and functional adaptations are related to these different insemination modes including peculiar accessory structures present both in male and female. In fact in more derived taxa the male chelicerae show peculiar structures, likely adapted to a more precise manipulation of the spermatophores, and related to other peculiar specialized structures in the females and to different insemination modes. Actually, corresponding females show a modified genital system and can be provided with specialized structures to receive the spermatozoa (sperm access system). Moreover, among Gamasida, those taxa provided with modified chelicerae in males show a displacement of the male genital opening in a presternal position to facilitate the transfer of the spermatophore to the chelicerae. These accessory structures enclose very important behavioural, functional and systematic implications still not full explained. Here a review is reported with data regarding the taxa investigated among Gamasida with perspectives for future researches.

Anatomy and ultrastructure of the prosomal salivary glands in the water mites *Piona carnea* (Koch, 1836) and *Teutonia cometes* (Koch, 1837) (Acariformes: Hydarchnidia)

Andrey Shatrov
Zoological Institute of the Russian Academy of Science, Russia

Prosomal salivary glands of the water mites P. carnea and T. cometes were examined both on serial semi-thin sections and in TEM. P. carnea possess four gland pairs, which can be termed medial, intermedial, lateral and ventral, and the medial glands, as in larvae of this species, have unique arrangements one after another on the middle body line. The ducts of the medial and intermedial glands are fused together separately from the ducts of the lateral and ventral glands, which join with the common salivary duct. Both gland ducts are fused and open into the subcheliceral space. Glands in P. carnea are composed of the single very large alveolus built up of the secretory cells arranged around extremely voluminous intra-alveolar cavity (central lumen) and possess similar secretory vacuoles of moderate electron densities, large nuclei and numerous cisterns of rough endoplasmic reticulum. In contrast with P. carnea, adult mites T. cometes have only two pairs of extremely large salivary glands, which may be termed dorsal and ventral. They organize similar to the glands of P. carnea, and their gland ducts fuse together and with the common salivary (podeocephalic) duct, which is finally opened into the subcheliceral space. The cells of the salivary glands of this species are filled with secretory vacuoles of different sizes and densities. Thus, in the adult water mites T. cometes, in comparison with P. carnea, oligomerization of the salivary glands number up to two pairs has apparently occurred.

Presumed paternal genome loss during embryogenesis of predatory phytoseiid mites

Shingo Toyoshima[1], Hiroshi Amano[2]
[1]NARO Institute of Vegetable and Tea Science, Japan, [2]Kyoto University, Japan

The reproductive system of predatory phytoseiid mites is thought to be pseudo-arrhenotoky or paternal genome loss (PGL), which would place it between two reproductive systems: bisexual and arrhenotokous reproduction. PGL itself is a remarkable event during embryogenesis. In addition, the reproductive system of phytoseiid mites has interested scientists in terms of its evolutionary significance, and elaborate hypotheses have been developed to clarify phytoseiid reproduction. However, these hypotheses were based on cytological evidence from other animal groups, with insufficient experimental evidence from phytoseiid mites. Therefore, PGL in phytoseiid mites is not confirmed, just presumed. Cytological and histological events during embryogenesis in phytoseiid mites need to be elucidated to supplement the theoretical approaches. In this article, additional histological and genetic evidence of phytoseiid reproduction is presented to better understand the evolutionary significance of paternal genome loss during embryogenesis.

Social Insects

Not quite eusocial? There are plenty of fun and merits in studying subsocial insects

Jae Chun Choe
Ewha Womans University, Republic of Korea

The evolution of sociality is considered a major transition of evolution. Among the myriads of animals that live solitarily, how and why only the "handful' of animals have reached the levels of sociality is thus a question to be answered. Subsocial insects, in particular, has been a subject of considerable interests, not only because of their "admirable" nature but also for their potential significance in understanding the evolution of eusociality. Two primary evolutionary routes to eusociality have been proposed: the subsocial route and the semisocial route. Due to its inclusive properties of the term 'subsocial', however, many of the examples used to support both the subsocial and semisocial route could fall in the category of subsociality. For the evolution of eusociality, empirical study still lags behind theoretical analysis. Studies of subsocial insects could provide much needed empirical data on both the proximate and ultimate causes of social evolution. In this account, I will try to briefly review the history of the study of sociality in insects, highlight some key issues in the study of subsocial insects, and dare to comment on the recent debate over the importance of kin selection.

Social regulation of task-related plasticity in circadian rhythms in honey bee (*Apis mellifera*) workers

Guy Bloch
Hebrew University of Jerusalem, Israel

Division of labor in honey bees is associated with plasticity in circadian rhythms. Forager bees (typically > three weeks of age) show strong behavioral and molecular circadian rhythms with higher activity during the day. Younger bees that typically care for ('nurse') the brood are active around the clock with attenuated oscillations in clock gene expression. Genome- wide microarray analysis found 160 and 541 transcripts exhibiting significant sinusoidal oscillation in nurses and foragers, respectively, with peaks of expression distributed throughout the day in both task groups. Nurses that were transferred from the hive to a constant lab environment switch to activity with strong circadian rhythms and onset of activity during the subjective morning. These findings suggest that some pacemakers measure time and regulate circadian processes even in around the clock active nurse bees. We used social manipulations for studying the regulation of plasticity in circadian rhythms. We found that nurse-age bees that were caged on broodless combs inside or outside the hive have strong circadian rhythms in activity and clock gene expression. By contrast, same-age full-sister bees that were caged on brood containing combs were active around the clock with attenuated clock gene oscillations, similar to the pattern typical to nurse bees. Nurse age bees for which we removed the flagella of the antenna, tended the brood like intact nurses, but were more active during the day. Taken together these studies suggest that signals from the brood are perceived by the nurse flagella and regulate plasticity in the circadian system.

Antioxiant and antibacterial activity of different floral honeys from Western Ghats of Karantaka

Shubharani Rmanath[1], Anita Menon[2], Mahesh Mr[3], Sivaram Venkataramegowda[4]

[1]Bangalore University, India, [2]Bangalore University, India, [3]Azyme Biosciences Private Limited Jayanagar, India, [4]Bangalore University, India

Honey has a wide range of therapeutic properties which depend largely on floral sources. In this study six Apis cerana honey samples collected from different locations of Western Ghats of Karnataka were screened for total phenolic content, potential antioxidant activity and antibacterial effects. The antioxidant properties of these samples were assessed by DPPH (2, 2-diphenyl -1-picrylhydrazyl) and ABTS+ radical scavenging activity. The antibacterial tests were done by using gram-positive (Staphylococcus aureus) and gram-negative (Pseudomonas aeruginosa, Klebsiella pneumonia, and Eschiershea coli) bacteria. In addition the pH and color intensity of the honey samples were analyzed. The result of the study demonstrates that, antioxidant activity was low in light color honey and high in dark honey. The color of the honey samples analyzed in this study was variable and ranged from pale yellow to dark brown. All the 6 honey samples did not show the bacterial growth inhibition against Staphylococcus aureus.

The clypeal gland in *Pyramica sauteri*, a novel exocrine structure in ants, and its role in prey capture

Johan Billen[1], Ca-Sin Lam[2], Chung-Chi Lin[3]

[1]University of Leuven, Belgium, [2]National Changhua University of Education, Taiwan, [3]National Changhua University of Education, Taiwan

We report on the occurrence of a novel exocrine gland of the dacetine ant Pyramica sauteri. The gland is formed by bicellular class-3 units that open through small pores on the upper side of the peculiar platform-like clypeus. The gland most probably is the origin of the 'labral secretion' that has been reported in literature, and that plays a role in the capture of collembolan prey. Our observations confirm that prey capture involves the stealthy approach of the ant towards a collembolan, which is attracted to the upper clypeal portion of the ant's head, which corresponds with the region where the glandular cells open. When the prey is licking the clypeus of the crouching and motionless worker, it is within the reach of the ant's mandibles and will be seized and carried to the ant nest. Chemical analysis using a SPME-fiber fixed to a micro-injector allows precise small area sampling and shows a similar pattern of hydrocarbons of various regions of the head, but also reveals that the upper clypeal region of foraging ants contains heptadecane and octadecane as two additional compounds, that appear to play a role as prey attractants.

Termites, the other social insects

Judith Ingrid Dr Korb
University of Osnabrueck, Germany

Termites are the second large group of social insects and their complex societies date back more than 130 million years. Unlike the social Hymenoptera, termites find their roots alongside the cockroaches and are basically 'social cockroaches'. This different ancestry is reflected in the organisation of their societies: e.g. Termites are hemibetabolous insects and their workers are larvae, while the workers of the holometabolous social Hymenoptera are adults and the larvae are dependent young. Yet the striking apparent similarity between ants and termites lead to the general assumption that the driving forces of their social evolution were similar. This is debated: The first sterile caste that evolved in termites was the soldier caste which is present in all species (exception: few apical taxa). The role of the workers is less clear. In higher termites (Termitidae) they clearly are an altruistic caste highly engaged in brood care. Yet in the phylogenetically basal lower termites brood care seems to be less developed or absent in wood-dwelling species that spend their entire colony life in a single piece of wood (one-piece nesting termites). Only in taxa that forage outside their nest (foraging species; multiple-pieces nesting termites) brood care becomes prominent. As the wood-dwelling life style is thought to be ancestral in termite's evolution this implies that the forces of social evolution largely differed in termites and social Hymenoptera and that defence played a major role in termites. This has important consequences when applying inclusive fitness theory to worker evolution.

Social Insects

A colony size "sensing" mechanism in an ant

Kazuki Tsuji[1], Ken Sugawara[2], Tomonori Kikuchi[3]

[1]University of the Ryukyus, Japan, [2]Tohoku Gakuin University, Japan, [3]Chiba University, Japan

Colonies of social insects are often regarded as super organisms. Individuals are like cells and organs of a colony. As individual organisms change their characteristics as they grow, colonies of social insects also change their behavior and other traits in response to the colony size. How individual colony members can "sense" their own colony size is, however, generally unknown. In this talk we show the first explicit mechanism of colony size related behavioral regulation. In colonies of the queenless ponerine ant, Diacamma sp. from Japan, a mated worker (gamergate), which effectively monopolizes reproduction as the functional queen, regularly patrols in the nest to inform her presence to other unmated workers and to inhibit their reproduction. Interestingly, she spends longer time in patrolling as the colony becomes larger. We show a simple feedback mechanism, relying on individual contacts, regulates this activity shift in response to changing colony size.

Provisioning control by females of the earwig, *Anisolabis maritima*: Does she adjust provisioning according to the young's need?

Seizi Suzuki
Hokkaido University, Japan

Provisioning to young is an important form of parental care and is expected to improve young survival and growth. Because the presence of some cost is expected in provisioning by parents, some parents have a flexible investment dependent upon their young's need, to minimize the costs of current reproduction. The evolution of offspring begging signals is predicted based on an evolutionary resolution of this conflict. Anisolabis maritime is a cosmopolitan species of earwig and shows a subsocial behavior where females tend clutches of eggs in soil burrows and progressively bring food to their nest after hatching. I will report on: 1) what signal affects provisioning to young, 2) whether or not flexible control of food provisioning occurs in this species.

Provisioning call by mothers of a subsocial shield bug

Shintaro Nomakuchi[1], Lisa Filippi[2]

[1]Saga University, Japan, [2]Hofstra University, U.S.A.

Offspring of many animal species solicit food from parents using begging signals, while parents manipulate offspring behavior to optimize fitness using various signals. Female Parastrachia japonensis (Heteroptera) provision nests with drupes of the host tree. Provisioning females were recently heard emitting a low-pitched fluttering sound that we characterized in the field using a contact microphone. A single calling event consisted of multiple sound bouts of varying lengths. A fast Fourier transform (FFT) analysis revealed a frequency range of 0~1 kHz. We tentatively designated it 'provisioning call'. Females emitted the call only upon returning to their nymph-containing nests with a drupe. Moreover, nymphs quickly gathered to the drupe while the female was calling. Because nymphs usually hide in crevices throughout the nest debris while the mother is foraging, we suggest that the provisioning call functions to induce nymphs to gather and feed synchronously on newly provisioned drupes. A playback experiment indicated that significantly more nymphs gathered on a drupe with the playback call than without the call. To the best of our knowledge, this is the first report of a parent producing sound and/or vibration signals directly to offspring at repeated progressive provisioning events in a subsocial insect.

Mothers regulate synchronous hatching: Maternal vibration in a subsocial burrower bug, *Adomerus rotundus*

Hiromi Mukai[1], Mantaro Hironaka[2], Sumio Tojo[3], Shintaro Nomakuchi[4]

[1]Kagoshima University, Japan, [2]Hamamatsu University School of Medicine, Japan, [3]Saga University, Japan, [4]Saga University, Japan

In some social egg-laying species, parents provide special care for embryos at hatching. A subsocial burrower bug, Adomerus rotundus (Heteroptera: Cydnidae) exhibits maternal care, such as defense against predation and providing food. We found that in A. rotundus, mothers displayed a physical vibration (shaking the body rhythmically), while maintaining the egg-guarding posture, ie., holding the egg mass under the thorax, between the forelegs and midlegs. The occurrence of this behaviour apparently had a peak, coinciding with the time when most embryos synchronously started to emerge from their shells. We examined whether A. rotundus mothers induce synchronous hatching by this physical vibration, and tested two hypotheses: that the maternal vibration assists to improve the success of hatching, and that the vibration regulates the hatching schedule. First, we carried out an experiment where the mother was removed just before hatching to investigate the effect of the presence of a mother on hatching rate and hatching synchrony. The control broods, which experienced continuous guarding from the mother, showed a high hatching rate and synchronous hatching. On the other hand, although the experimental broods, which were isolated from the mother, also showed a high hatching rate, they hatched asynchronously. Second, we experimentally exposed mature egg masses to an artificial vibration and monitored the hatching pattern. Synchronous hatching was induced by the artificial vibration. These results strongly suggest that A. rotundus mothers actively regulate synchronous hatching by physical vibration, but they do not assist the embryos in hatching.

Use of multiple compass references in path integration of the subsocial burrower bug, *Adomerus rotundus*

Mantaro Hironaka[1], Narumi Baba[2], Takahiko Hariyama[3]

[1]Hamamatsu University School of Medicine, Japan, [2]Kyushu University, Japan, [3]Hamamatsu University School of Medicine, Japan

In several species of subsocial heteropterans, the mother bug searches for plant seeds on the ground and provisions them to young in the nest, such as ants do. Therefore, they have acquired remarkable navigation systems to perform this foraging navigation. A female Adomerus rotundus (Heteroptera: Cydnidae) leaves the nest, searching tortuously for a seed around the host plant by walking, and homes directly back when it finds a seed. In this foraging excursion, the female mainly uses a path integration system based on a visual compass referencing canopy gaps. However, canopy gaps seem to be quite unreliable as reference points because they easily disappear from sight by obstacles such as tree trunks and stems and leaves of plants. One potential solution for this problem is that the navigator independently processes multiple compass references beforehand to be prepared for the disappearance. To determine whether the bug independently uses two different visual references in path integration, we let individual females forage in an experimental arena, setting two LED lights from different elevations. We observed the homing behaviour of female bugs when the light was turned off and/or shifted. These experiments revealed that A.rotundus can independently use two different visual points as compass references in path integration. This unique navigational capacity seems to have evolved in order to compensate for the unreliable compass reference in A. rotundus.

Subsocial habits and phylogenetic relationships of Neotropical Chrysomelinae (Coleoptera, Chrysomelidae)

Donald Windsor
Smithsonian Institution, Panama

Subsociality, defined narrowly here as the guarding of offspring by a parent may not be a rare condition in Neotropical Chrysomelinae. Recent observations suggest it is an underreported behavior because many taxa are rare in nature, are highly seasonal in reproduction and display tight associations with a small subset of available host plants. We review possible phylogenetic relationships among selected subsocial and solitary taxa living in Central and South America.

Selection of old nesting sites by *Apis dorsata* in the Northern parts of Thailand

Ratna Thapa[1], Myeong-Lyeol Lee[2], Yong-Soo Choi[3]
[1]Mae Fah Luang University, Nepal, [2]NAAS, Republic of Korea, [3]NAAS, Nepal

A total of 27 nesting sites, 14 (52.0%) nesting sites in Chiang Mai and 13 (44.1%) nesting sites in Chiang Rai, the northern parts of Thailand were marked and monthly visited during 2008-2010. The selected nesting sites based on remnants of old combs (a) full comb, (b) half remnant comb, (c) honey comb, and (d) trace of combs were classified into four categories. The results showed that A. dorsata reoccupied four types of nest substrates: buildings (77.8%), water tanks (26.0%), trees (7.4%), and metal frames (7.0%). The full old remnants combs attracted 6 colonies (28.6%), half combs 8 colonies (38.1%), honey combs 3 colonies (14.3%), and traces 4 (19.1%) colonies. In the 2008, 2009, and 2010, 4, 4 and 3 colonies in Chiang Mai and 3, 7 and 5 colonies at Mae Fah Luang University, Chiang Rai reoccupied the same old nesting sites respectively. The average nesting period of A. dorsata colonies in Chiang Mai was 5.5?2.7 months, and in Chiang Rai was 6.2?5.1 months.

Detection technologies of honeybee diseases in Korea

Boram Lee[1], Van Phu Nguyen[2], Byoungsu Yoon[3]
[1]Kyonggi University, Republic of Korea, [2]Kyonggi University, Republic of Korea, [3]Kyonggi University, Republic of Korea

Honeybee plays a key role in the human and natural world. The economically most important honeybee was formerly considered to be infected by various pathogen. This study describes techniques used to diagnose honeybee diseases. Major detection methods for honeybee diseases include PCR, LAMP, and immunochromatographic assay. The following diseases were diagnosed based on PCR and real-time detection methods: american foulbrood (AFB), european foulbrood (EFB), chalkbrood, stonebrood, nosema, sacbrood virus (SBV), deformed wing virus (DWV), black queen cell virus (BQCV), kashmir bee virus (KBV), chronic bee paralysis virus (CBPV), israel acute paralysis virus (IAPV), Cloudy Wing Virus (CWV). A micro-scale chip-based real-time PCR system based detection method, termed ultra-rapid real-time PCR, was developed to rapidly and quantitatively detect honeybee diseases within 10 min. This method has detected 9 of 12 honeybee diseases mentioned above. Loop-mediated isothermal amplification method (LAMP) has also used to detect 9 of 12 honeybee diseases with high specificity, efficiency, and rapidity under isothermal conditions without expensive equipments. On the other hand, immunochromatographic assay was developed to detect AFB using specific monoclonal antibodies against Paenibacillus larvae spores. Although PCR methods are still being applied at present time, PCR related rapid kits are being developed day by day. Therefore, detection technologies are rapidly being developed, which may facilitate the detection of honeybee diseases as well as monitor for natural infection of Apis mellifera L.

Honeybee and ectoparasitic mite: Modeling approach to understand the complex

Dongwon Kim[1], Chuleui Jung[2]
[1]*Andong National University, Republic of Korea,* [2]*Andong National University, Republic of Korea*

Honeybee is attracting more attention by the public after CCD. Ectoparasitic varroa mite is the most threat to honeybee health. To understanding the complex interaction between honeybee and varroa mite, we tried to model both species dynamics. Mathematical model can provide effective framework for guiding the implementation or simulated studies which sometimes require substantial time, labor and cost. Basic frameworks of the model were employed from the published information. Field monitoring data were used for adjustment of the sub module or validation of the behaviors. Using this model, we provide some scenario for management of the varroa relative to the integrated mite management (IMM) scheme.

Current status of managed insect pollinator in Korea

Hyung Joo Yoon
National Academy of Agricultural Science, RDA, Republic of Korea

We investigated the use rate and number of commercial beesfor the pollination of 10 major horticultural crops and fruit trees in Korea. The use rates of bumblebees for 10 major horticultural crops and fruit trees were approximately 7.9% and 2.8% in 2010, respectively. The use numbers of bumblebees as pollinators was more than 64,345 colonies which included 51,400 for 10 major horticultural crops and 12,945 colonies for 10 major fruit trees, in 2009. The use rate of honeybees as a pollinator for 10 major horticultural crops in greenhouses and fruit trees were approximately 48.0% and 7.7%, respectively. The number of hives used for 10 horticultural crops and furit trees was estimated to be 305,216 and 32,386, respectively. The number of honeybees hives used for pollination of 10 major horicultural crops and fruit trees was estimated to be 337,602. The use numbers of honeybees as pollinators was more than 337,602 hives in 10 major horticultural crops and fruit trees, in 2009.The number of honeybee hives used as pollinators of outside crops, including many fruits and vegetables, was estimated to be more than 500,000. The value of honeybees as pollinators was estimated to be more than 8.5% to 15.0% of total Korean beekeeping products. The rate of use of mason bees for 10 major fruit trees was approximately 3.3%. The number of mason bees individuasl used for 10 major furit trees was estimated to be 1,350,000. The value of insect pollinators in 2010 in Korea was estimated at more than $45million.

Honeybee visiting and pollinator attracting characteristics of some honey plants as Black locust replacement in Korea

Jingyu Han[1], Sea-Hyun Kim[2], Moon-Sup Kim[3]

[1]Korea Forest Research Institute, Republic of Korea, [2]Korea Forest Research Institute, Republic of Korea, [3]Korea Forest Research Institute, Republic of Korea

The apiculture industry was depended on a black locust (Robinia pseudoacacia L.) over 70 percent of total honey production in Korea. The Korean apiculture industry was faced a crisis cause by deterioration of black locust. The deterioration was accelerated by disease and pest increase in the 2000s. The immediate cause of the crisis was disease, pest and anomaly climate but the root cause was absence of honey plant management. Fortunately, nowadays various researches are being carried out to find other honey plants which can use replacement of black locust because there is realized the importance of honey plant as honey resources. The amount of flowering, the number of honeybee visiting and nectar secretion was investigated as main factors in order to find useful honey plant. Korean raisin tree (Hovenia dulcis var. koreana Nakai), linden tree (Tilla amurensis Rupr.) and Korean evodia (Evodia daniellii Hemsl) were selected as the honey plant. In case of honeybee visiting, the number of honeybee visiting on Korean raisin tree were 200 form 12 pm to 13 pm, Black locust were 130 from 9 am to 10 am, Linden tree were 60 from 15 pm to 16 pm and Korean evodia were 40 form 15 pm to 16 pm. In case of nectar secretion, secreted nectar volume of Korean raisin tree, linden tree, Korean evodia and black locust were 4.15$\mu\ell$, 3.58$\mu\ell$, 3.13 $\mu\ell$ and 2.02$\mu\ell$ from a one flower.

Analysis of pollen in honey

Yong-Soo Choi[1], Soon ok Woo[2], In Pyo Hong[3], Sang Mi Han[4], Ratna Thapa[5], Gyu Ho Byon[6], Myeong Lyeol Lee[7]

[1]Rural development Agriculture, Republic of Korea, [2]Rural development Agriculture, Republic of Korea, [3]Rural development Agriculture, Republic of Korea, [4]Rural development Agriculture, Republic of Korea, [5]Rural development Agriculture, Thailand, [6]Rural development Agriculture, Republic of Korea, [7]Rural development Agriculture, Republic of Korea

This study reports the method of pollen analysis to classify honey samples according to floral sources, in samples from Korea. The pollens in honey have different molecular weights depending upon the honey floral sources. We were purified the pollen in honeys produced from mono-floral and multi-floral honey, respectively. Honey samples used in this study differ due to plant sources, collection periods, each honeys were centrifuged by sucrose density gradient. This study describes a simplified method for determining the total amount of pollen grains and the relative frequencies of pollen from various plant sources in honey. In many commercially obtained honey samples from Korea beekeepers and China store. Pollen of plant species from Prunus sargentii, Castanea crenata var. dulcis, Robinia pseudoacacia and premium grade Honey. The results of this study indicate that pollen in was on different concentration followed by plant source(honey). The data reflects the pollen situation of the honey were particular honey was produced and the identification of plant origin based on the presence of a combination of pollen types of that particular floral source. The pollens in honey have different genotypes upon the plant sources. Analysis of pollen 16s rDNA result showed different amplification form by PCR. The use of sucrose density gradient and PCR combined with pollen identification proved useful in characterizing honey samples from different botanical origins.

Organic beekeeping and organic honey in Thailand

Siriwat Wongsiri[1], Ratna Thapa[2], Pichai Kongpitak[3]
[1]Maejo University, Thailand, [2]Mae Fah Luang University, Thailand, [3]Chiang Mai University, Thailand

Organic honey, is a pure healthy honey from unpolluted virgin forests or from unpolluted organic agricultural orchards, free from pesticides or chemical environmental pollutants. The organic honey in the kingdom of Thailand is new and innovation research since no records in the literatures. Traditional beekeeping in Thailand is possible to be changed to the organic beekeeping by educate the beekeepers. The average annual honey production of a traditional hive is 3-5 kg/annum, while that of a box hive is 5-20 kg/annum. In the country, about 5000 metric tons of honey are produced annually. The types of honeys produced in Thailand are well known according to their seasons and their botanical origins. These types include Eupatorium odortum Dimcarpus fumatus, Hilianthus annus, Sesamum orientale and Croton roxburghii honeys. The prices of these honeys vary from USD 10 to USD 20 per/kg. Longan honey is highly demand in the country and this kind of honey can be exported as the organic honey. The majority of beekeepers extract honey by the traditional straining method, while some beekeepers with modern hives extract their honeys using honey extractors. This method has to be modified to be the standard or organic beekeeping methods. Now in China, organic honey is produced from the Asian honey bee, Apis cerana more than one million colonies in the forest bee flora and the beekeeping practice of Asian honeybees no need to use pesticides and anti-biotics.

Study of purified honeybee (*Apis mellifera*. L) venom from Korea

SangMi Han[1], KwangGill Lee[2], Soon Ok Woo[3], In Phyo Hong[4], YongSoo Choi[5], ManYoung Lee[6], MyeongLyeol Lee[7], KwanKyu Park[8]

[1]National Academy of Agricultural Science, RDA, Republic of Korea, [2]National Academy of Agricultural Science, RDA, Republic of Korea, [3]National Academy of Agricultural Science, RDA, Republic of Korea, [4]National Academy of Agricultural Science, RDA, Republic of Korea, [5]National Academy of Agricultural Science, RDA, Republic of Korea, [6]National Academy of Agricultural Science, RDA, Republic of Korea, [7]National Academy of Agricultural Science, RDA, Republic of Korea, [8]Catholic University of Daegu, Republic of Korea

The aim of the study was to the determination quantitatively of the major constituents of honeybee (Apis mellifera L.) venom from Korea. The chemical composition of honeybee venom from Korea were evaluated. Melittin content varied from 48.5 to 67.2 and averaged 50.7%. Apamin content camewithin a range of 2.0 to 3.2, and averaged 2.8%, and phospholipase A2 content was between 10.8 to 14.5, averaging 12.8%. There is no statistically significant differences for the content of the main component compared standard honeybee venom to domestic honeybee venom. Acne vulgaris is a chronic inflammatory disorder of the sebaceous follicles. The present study was conducted to evaluate the antimicrobial property of honeybee venom (BV) against the etiologic agents of acne vulgaris and the pharmacological activities of BV have been used in wound healing for centuries. Incubation of the skin bacteria P. acnes, clindamycin-resistant P. acnes, Staphylococcus epidermidis or Streptococcus pyrogenes with BV yielded the minimal inhibitory concentration (MIC). To study wound healing, full thickness skin defects were produced on the dorsal area of mice. The wound sizes were small in the BV group compared to the Control and Vaseline groups. The BV group demonstrated decreased TGF-β1, fibronectin and VEGF mRNA levels and increased collagen-I mRNA levels. These data suggested that BV has effective antimicrobial and anti-inflammatory activity against P. acnes and we suggest that BV is an alternative treatment for antibiotic therapy of acne vulgaris and significant wound healing activity.

RT-PCR analysis of deformed wing virus in the workers of honeybee subspecies *Apis mellifera* carnica

Muniswamyreddy Shankar Reddy[1], Pattabhiramaiah Mahesh[2], Dorothea Brueckner[3]
[1]Bangalore University, India, [2]Bangalore University, India, [3]University of Bremen, Germany

Deformed wing virus (DWV) is a positive-strand RNA virus that infects European honeybees (Apis mellifera L.) and has been isolated from the brains of aggressive bees in Japan. DWV is known to be transmitted both vertically and horizontally between bees in a colony and can lead to both symptomatic and asymptomatic infections in bees. In environmentally stressful conditions, DWV can contribute to the demise of a honeybee colony. Application of RT-PCR confirmed the presence of DWV infection in the honeybee brain which could adversely affect critical sensory functions and alter normal bee behavior.

Declining populations of *Apis cerana* - a threat to agricultural sustainability in Asia

Dhram Pal Abrol[1], Muniswamyreddy Shankar Reddy[2]
[1]*Sher-e-Kashmir University of Agricultural Sciences & Technology, India,* [2]*Bangalore University, India*

The Asiatic honeybee Apis cerana is widely distributed throughout Asia, as far north as Japan and China as far west as Iran and Afghanistan and south into India and Sri Lanka. The honeybee Apis cerana which is adapted to the local climatic conditions through centuries of natural selection is threatened and on decline due to changes in land use and intensification of agriculture leading to a loss of wild habitat, reduction in species availability for feeding, and death from pesticides; on the other hand introduction of Apis mellifera into indigenous areas of Apis cerana is encouraging farmers to replace Apis cerana with the exotic bee, and introducing diseases and parasites against which Apis cerana has no resistance. Introduction of disease through exotic species is a widespread problem. The indigenous honeybee species such as Apis cerana, Apis laboriosa, Apis dorsata and Apis florea have been co-existing for centuries without transfer of diseases and parasites. When Apis mellifera was introduced it brought with it European Foul Brood (EFB) and Acarine disease. Other bee species have also been affected. The Apis mellifera parasite Melisococcus plutonius has been detected in colonies of Apis laboriosa, for example. There has also been transfer in the opposite direction: the Apis dorsata parasite Tropilaelaps clareae transferred to Apis mellifera colonies, and was spread by them. The major factor for decline in populations of Apis cerana has been the non-acceptability of this species by beekeepers and the farming community in comparison to Apis mellifera. The details will be discussed.

Positional cloning and functional analysis of candidate genes responsible for AcNPV susceptibility in silkworm, *Bombyx mori*

Jian Xu[1], Kimiko Yamamoto[2], Jae Man Lee[3], Hiroaki Mon[4], Takahiro Kusakabe[5]

[1]Kyushu University, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]Kyushu University, Japan, [4]Kyushu University, Japan, [5]Kyushu University, Japan

Baculoviruses were first identified as insect-specific pathogens. Autographa californica nucleopolyhedrovirus (AcNPV) is generally considered to be unable to replicate in domestic silkworm and its cell lines. In 2007, we reported that several silkworm strains including d17 showed remarkable susceptibility to recombinant AcNPV expressing firefly luciferase under the control of the A3 actin promoter. In this study, the susceptible and resistant silkworm strains, d17 and k45, were used for genetic linkage analysis of the AcNPV-susceptible trait. The results indicated that the AcNPV sensitivity is a single gene controlled trait and also a recessive inheritance. By positional cloning, we identify a region tightly linked to this trait to approximately 255.6 kb located on the scaffold Bm_scaf63 on the chromosome 3. Eight candidate gene models were found in the region after searching the silkworm gene model database. These gene candidates were then cloned from the d17, k45 and p50T strains. Sequence analysis indicated that among these eight gene candidates, two genes carried amino acid substitutions. The mRNA expression levels of two genes were significantly increased in the resistant strain k45. To investigate the gene functions related to silkworm's susceptibility to AcNPV, we compared the AcNPV sensitivity of the BmN4 cells, in which the candidate genes were knocked down or over-expressed. The results suggested that there was no significant affection on the AcNPV sensitivity. Consequently, more systematic research is needed to obtain a convincible conclusion of which candidate gene is really involved in AcNPV susceptibility.

The host range of *Bombyx mandarina* nucleopolyhedrovirus S2 covers those of *Bombyx mori* and Autographa californica MNPV

Ruolin Cheng[1], Yipeng Xu[2], Chuanxi Zhang[3]
[1]Zhejiang university, China, [2]Zhejiang university, China, [3]Zhejiang university, China

Bombyx mandarina nucleopolyhedrovirus S2 (BomaNPV S2) was isolated from a diseased larva of the wild silkworm, Bombyx mandarina. Notably, BomaNPV S2 exhibits a distinguishing feature that its host range covers those of Bombyx mori NPV (BmNPV) and Autographa californica MNPV (AcMNPV). It can replicate in Bombyx mori (Bm) cells, as well as Spodoptera frugiperda (Sf) cells and Trichoplusia ni (Tn) cells. However, ODVs of BomaNPV S2 in Bm cells contain only one nucleocapsid (SNPV), but one to many nucleocapsids (MNPV) in High Five cells (Tn-5B1-4). The complete genome sequence of BomaNPV S2, as well as its predicted ORFs, was determined and compared to the genome sequence of close relatives. Comparison results showed that most of BomaNPV S2 genome sequence are covered by BmNPV (BmNPV T3 or BomaNPV S1), but several regions seem more similar to those of AcMNPV. This might explain why BomaNPV S2 covers host ranges of BmNPV and AcMNPV. Further experiments of recombined viruses infection demonstrate that gp64 plays an important role in the host range determination of BomaNPV S2.

Control of Baculovirus Infection by host MicroRNA

Yu-Chan Chao[1], Yueh-Lung Wu[2]
[1]Academia Sinica, Taiwan, [2]Academia Sinica, Taiwan

Although baculoviruses Autographa californica multiple nucleopolyhedrovirus (AcMNPV) and Bombyx mori nucleopolyhedrovirus (BmNPV) have highly homologous genomic sequences, their host specificity is different. The former can infect insect Sf21 cells, but not silkworm BmN cells. Previous study showed that baculovirus p143 gene plays a key role in host specificity. When the p143 gene of AcMNPV was replaced with that of BmNPV, then AcMNPV was able to infect silkworm. Since the difference in the p143 gene sequences between these two viruses is minimal, three putative miRNAs identified from the silkworm genome that might specifically target to the p143 gene of AcMNPV were studied. Loop-PCR analysis showed that two of these miRNAs were expressed in BmN cells. Further experiments showed that the transfection of synthesized miRNAs, could significantly suppress the expression of p143 gene in Sf21 cells. Furthermore, these miRNAs were able to significantly inhibit the production of AcMNPV in Sf21 cells. Since Drosha and Dicer play crucial roles in the miRNA pathway, siRNAs against Drosha- and Dicer-like genes in BmN cells were used to separately knock-down these two genes. AcMNPV, with its own p143 gene, was then able to infect BmN cells successfully. Therefore, although previous reports have indicated that the differences in amino acid content of P143 may play a role in host specificity, our results suggest that miRNAs generated in different host cells may be more crucial for determining host specificity of an infecting virus to silkworm BmN cells.

Attenuation of the insect antimicrobial response after baculovirus infection.

Agata Karolina Jakubowska[1], Heiko Vogel[2], Salvador Herrero[3]
[1]Universitat de Valencia, Spain, [2]Max Planck Institute for Chemical Ecology, Germany, [3]Universitat de Valencia, Spain

Using genetic information derived from the transcriptome of Spodoptera exigua larvae we designed an expression microarray to decipher the transcriptional response of S. exigua to pathogenic baculovirus infections. Custom microarrays representing around 30,000 unigenes were used to determine the genes differentially expressed in S. exigua Se301 cells challenged with two baculoviruses, a highly specific (SeMNPV) and a generalist virus (AcMNPV). Expression changes were monitored after 4, 12, and 36 hour post infection (h.p.i). Although we observed a fast increase in the number of regulated genes with the progressing infection, host transcriptional shut-down was not observed. Se301 cells responded differentially to SeMNPV and AcMNPV, with more genes being regulated after the challenge with the specific virus. Under our conditions, at 36 h.p.i around 1500 unigenes were commonly regulated in response to both viruses. Among the up-regulated unigenes, we found a few repat family genes, as well as many genes responsible for signal transduction, ATP processing, chitin structure and metabolism and hormonal regulation. Interestingly, among the down-regulated genes we found many unigenes with homology to genes playing different roles in the insect antibacterial response. Given the clear changes in the expression profiles of antibacterial genes as well as other immune related genes we have further investigated the impact of viruses on the intestinal microbiota as well as the viral infection process in the absence and presence of intestinal microbiota. We will discuss the importance of intestinal bacteria in viral infections and propose possible mechanisms of viral regulation of the host immune response

Functional analysis of apoptosis suppressor genes encoded by *Lymantria dispar* multiple nucleopolyhedrovirus

Hayato Yamada[1], Koji Kitaguchi[2], Michihiro kobayashi[3], Motoko Ikeda[4]
[1]Nagoya University, Japan, [2]Nagoya University, Japan, [3]Nagoya University, Japan, [4]Nagoya University, Japan

Ld652Y cells derived from the gypsy moth, Lymantria dispar, readily undergo apoptosis following infection with various nucleopolyhedroviruses (NPVs), while Ld652Y cells are permissive for productive infection of L. dispar multiple NPV (LdMNPV) without apoptosis induction. LdMNPV encodes two inhibitor of apoptosis proteins (Ld-IAP2 and Ld-IAP3), and we found that neither Ld-IAP2 nor Ld-IAP3 was capable of suppressing apoptosis in S. frugipertda Sf9 cells induced by infection with vAcΔp35, a recombinant Autographa californica MNPV defective in anti-apoptotic gene p35, suggesting that LdMNPV encodes apoptosis suppressor other than IAPs. Thus, we conducted genome-wide screening with LdMNPV cosmid library, and identified a novel LdMNPV apoptosis suppressor gene, apsup, responsible for suppressing apoptosis in vAcΔp35-infected Ld652Y cells. Transient expression assay demonstrated that Apsup also suppressed apoptosis of Ld652Y cells induced by nonviral stimuli such as exposure to actinomycin D and UV. In addition, RNAi-mediated knockdown of apsup expression induced apoptosis in LdMNPV-infected Ld652Y cells. Database search revealed that no characterized Apsup homologues were found, and domain search of Apsup identified no characteristic domains linked to possible functions. To examine the apoptosis suppression mechanism of Apsup, we cloned L. dispar initiator and effector caspases (ld-dronc and ld-caspase-1) which served as the dominant factors in apoptosis signal pathway. Coexpression analysis showed that Apsup suppressed apoptosis in Ld652Y cells by suppressing the activation of Ld-Dronc and/or Ld-Caspase-1. Further analyses of Apsup are in progress to provide insight into virus anti-apoptotic functions against apoptosis-dependent host defenses.

N-glycosylation engineering of baculovirus-silkworm glycoprotein expression system

Yudai Nagata[1], Hiroaki Mon[2], JaeMan Lee[3], Takahiro Kusakabe[4]
[1]Kyushu University, Japan, [2]Kyushu University, Japan, [3]Kyushu University, Japan, [4]Kyushu University, Japan

Baculovirus expression systems (BES) are popular and widely used to produce glycoproteins because insect cells are capable of transferring N-glycans to recombinant proteins at the same sites as those used for N-glycosylation in mammalian cells. While mammalian cells produce complex type N-glycans containing galactose and sialic acid, insect cells mostly produce tri-mannosylcore or paucimannosidic N-glycans. One of reasons for this difference is the presence of a highly specific N-glycan processing beta-N-acetylglucosaminidase (FDL) in insect cells. Furthermore, insect cells may lack several enzymes required for mammal type N-glycosylation. The difference in N-glycan structure attached to the recombinant proteins might compromise its activity in vivo or induce allergenic reactions in mammals. The BES has several advantages over mammalian protein expression system, therefore much effort has been expended to synthesize mammalian-like N-glycans in insect cells. In this work, we investigated the effect of RNAi-mediated depletion of BmFDL in the N-glycosylation of secretion proteins expressed using BES. We also introduced human alpha-1,6-mannosyl-glycoprotein 2-beta-N-acetylglucosaminyltransferase (hMGAT2), beta-1,4-galactosyltransferase 1 (hB4GALT1) and beta-galactoside alpha-2,6-sialyltransferase 1 (hST6GAL1) into silkworm cultured cells to provide the enzymes necessary for rebuilding the mammalian-like N-glycosylation pathway. We found that the molecular weights of recombinant glycoproteins were increased by the synergistic effects of FDL suppression and human glycogenes expression.

Baculovirus expression system as a platform for functional study of novel cellulases

Chia-Jung Chang[1], Tuan Hua David Ho[2], Yu-Chan Chao[3], Su-May Yu[4]
[1]Academia Sinica, Taiwan, [2]Academia Sinica, Taiwan, [3]Academia Sinica, Taiwan, [4]Academia Sinica, Taiwan

Wood feeding insects depends heavily on the secretion of a combination of cellulases, mainly endo-glucanases and other glucanases such as exo-glucanases and xylanases, for efficient digestion of the cellulosic materials. To date, although a high number of endo-1,4-beta-glucanases have been found in xytophagous insects, little is known about exo-1,4-beta-glucanases encoded in the genome of these insects. Here we report the identification and isolation of an exo-glucanase, designated as AmCel-5B, from the white spotted longhorn beetle, Anoplophora malasiaca. The insect cellulases and control fungal exo-1,4-beta-glucanase were expressed, characterized in the silkworm-baculovirus expression system and their enzymatic conditions were optimized. Interestingly, AmCel-5B is not only exhibited exo-beta-glucanase activity, but also with obvious endo-beta-glucanase activity. Furthermore, this enzyme is unique in that, although it recognizes Avicel, evidenced as an exo-beta-glucanase, it cannot recognize oligosaccharides smaller than cellohexaose. This may explain why longhorn beetle can well digest hard "living" wood, which contains primarily rigid long fibers. Although it is known that metal ions can enhance the activity of some cellulases, we further demonstrated that reducing agent could work synergistically with metal ions for significant activity enhancement of AmCel-5B. The discovery and investigation of an insect exo-glucanase should lead to a greater understanding of the mechanism for efficient digestion of cellulosic materials by wood feeding insects. The recombinant longhorn cellulases of baculovirus expression in silkworms were found to act synergistically with the commercial cellulases and beta-glucosidase to hydrolyze row agricultural waste. The test formulation can facilitate their potential applications in the production

Development of a bi-cistronic Bacmam vector for neural stem/progenitor cells

Jhe-Jhih Lin[1], Hong-Lin Chan[2], Tzong Yuan Wu[3]
[1]National Tsing Hua University, Taiwan, [2]National Tsing Hua University, Taiwan, [3]Chung Yuan Christian University, Taiwan

Development of a safe and efficient gene therapy vector for neuron-related disease is a critical challenge in neuroscience. Bi-cistronic baculovirus expression vector system (bi-BEVS) is capable to synthesis of high levels of recombinant proteins through one promoter and an internal ribosome entry site (IRES) in insect cell lines for biotechnological applications. Here, we developed a genetic delivery vehicle for production of recombinant proteins based on the bi-BEVS in mammalian cells. A recombinant baculovirus that express DsRed and EGFP protein, under the control of CMV promoter and a chimeric IRES are used to infect rat neural stem/progenitor cells (rNS/PCs). In addition, baculovirus-transduced rNS/PCs show enhanced production of recombinant proteins when used sodium butyrate, an HDAC inhibitor. Our study identifies a nevo approach to express proteins in rNS/PCs, may have beneficial applications in the neurodegeneration therapies.

Cellular responses to baculovirus transduction in human mesenchymal stem cells and induced pluripotent stem cells

Guan-yu Chen[1], Yu-Chen Hu[2]
[1]National Tsing Hua University, Taiwan, [2]National Tsing Hua University, Taiwan

Human mesenchymal stem cells (hMSCs) and mouse induced pluripotent stem cells (iPSCs) can be genetically modified with viral vectors and hold promise as a cell source for regenerative medicine, yet how hMSCs and iPSCs respond to viral vector transduction remains poorly understood, leaving the safety concerns unaddressed. Hereby we explored the responses of hMSCs and iPSCs against an emerging DNA viral vector, baculovirus (BV). First, we uncovered that BV transduction perturbed the transcription of 816 genes associated with 5 signaling pathways in hMSCs. Surprisingly, toll-like receptor-3 (TLR3), a receptor that generally recognizes double-stranded RNA, was apparently upregulated by BV transduction as confirmed by microarray, PCR array, flow cytometry and confocal microscopy. However, we did not find any TLRs activation after BV transduction in iPSCs. Cytokine array data showed that BV transduction of hMSCs triggered robust secretion of IL-6 and IL-8, but not of other inflammatory cytokines. In contrast, BV transduction of iPSCs only elicited mild immune responses. These data demonstrate, for the first time, that a DNA viral vector can activate the TLR3 pathway in hMSCs but not in iPSCs, and lead to a cytokine expression profile distinct from that in immune cells. These findings underscore the importance of evaluating whether TLR3 signaling cascade plays roles in the immune response provoked by other DNA vectors (e.g. adenovirus). Nonetheless, BV transduction barely disturbed the surface marker expression and only induced transient and mild cytokine response, thereby easing the safety concerns of using BV for hMSCs and iPSCs engineering.

Development of a baculovirus expression vector for insect cells and mammalian cells

Ming Kun Liu[1], Hong Lin Chan[2], Tzong Yuan Wu[3]
[1]National Tsing Hua University, Taiwan, [2]National Tsing Hua University, Taiwan, [3]Chung Yuan Christian University, Taiwan

Baculovirus Expression Vector System is recognized as an important tool for molecular biology and widely used in insect cells and mammalian cells. Development of a shuttle baculovirus expression vector which can function in both the mammalian cell as well as in insect cell would have a significant advantage. Previous studies have demonstrated that the internal ribosome entry site (IRES) derived from 5' untranslated region (5' UTR) of Rhopalosiphum padi virus (RhPV) can mediate cap-independent translation in mammals, plants and insect cells by in vitro translation system. Moreover, earlier studies in our laboratory revealed the presence of cryptic promoter activity in RhPV 5' UTR containing six TAAG motifs in baculovirus infected Sf21 cells. So, series of deletion experiments of the six baculovirus late promoter conservative motifs (TAAG) in the cDNA of RhPV 5' IRES were conducted to identify the specific motif which provide cryptic promoter activity of RhPV 5' IRES. Two tandem repeated TAAG motifs within 309 ~ 418 nts of the 579 nts was responsible for critical promoter activity in baculovirus infected Sf21 cells and the sequence segment was named RP110. Finally, a chimeric sequence was generated by fusing RP110 with cDNA derived 5'UTR of enterovirus 71 to generate an artificial sequence that can function as a promoter in baculovirus infected Sf21 cells and also provide IRES activity in mammalian cells. In conclusion, the chimeric sequence will facilitate the development of a bicistronic baculovirus shuttle expression vector that can express genes in insect cells as well as mammalian cells.

Sericin as industrial glue and as additive to tissue culture media

Michal Zurovec[1], Barbara Kludkiewicz[2], Tereza Staskova[3], Frantisek Sehnal[4]

[1]Biology Centre ASCR, Czech Republic, [2]Institute of Biochemistry and Biophysics PAN, Poland, [3]Biology Centre ASCR, Czech Republic, [4]Biology Centre ASCR, Czech Republic

Bombyx mori contains 3 sericin-encoding genes, of which Ser2 generates two mRNAs by alternative splicing. Putative translation products consist of 1740 and 882 amino acids, respectively, and are characterized by 50 repeats of the highly conserved motif DSEKAKPNDRSPSHK (residues conserved in all repeats are underlined) that is remarkably similar to the mussel adhesive plaque protein and to the adhesive trypanosome trans-sialidase. However, the blue mussel protein is rich in Tyr, whereas the sericin 2 proteins contain high proportion of polar residues and are low in Tyr. We examined possible exploitation of recombinant derivatives of sericin 2 in the cell cultures. Most cell types require attachment to a surface and the nature of this substrate has a major effect on cell growth. The performance of many cell types can be dramatically improved by coating dishes with positively charged polymers, (i.e., poly-D-lysine), or tethered adhesion molecules (AMs), including laminin and collagen. We found that crude sericin extracts can spread even over hydrophobic surfaces that cause other water solutes (including poly-D-lysine) to bead up into droplets. We have tested coating of plastic dishes with several natural and recombinant Bombyx sericins for their ability to support growth of Drosophila Cl8+ cells and of the NIL-2 fibroblast-like cells of Syrian hamster. The cells did not grow and mostly perished within 48 hrs in untreated polystyrene plastic dishes, but survived well in dishes coated with truncated recombinant sericin variants (30.2 ? 67.6 kDa) containing the repeats.

Display of *Bombyx mori* alcohol dehydrogenases on the *Bacillus subtilis* spore surface

Keping Chen[1], Peng Lu[2]
[1]*Jiangsu University, China,* [2]*Jiangsu University, China*

Alcohol dehydrogenases (ADHs) are oxidoreductases catalyzing the reversible oxidation of alcohols to corresponding aldehydes or ketones accompanied by nicotinamide adenine dinucleotide (NAD) or nicotinamide adenine dinucleotide phosphate (NADP) as coenzyme. ADHs attract major scientific and industrial interest for the evolutionary perspectives, afforded by their wide occurrence in nature, and for their use in industrial synthesis. However, the low activity of ADHs under extremes of pH and temperatur often limits their application. To obtain ADH with high activity, in this study, we used Bombyx mori alcohol dehydrogenases (BmADH) as foreign gene and constructed a recombinant integrative plasmid pJS700-BmADH. This pJS700-BmADH was transformed into Bacillus subtilis by double cross-over and produced an amylase inactivated mutant. The fusion protein containing BmADH was expressed on the spore surface and recognized by BmADH-specific antibody. We also assayed the alcohol dehydrogenase activity of the fusion protein together with the mative BmADH at different pH and temperature levels, which indicated the recombinant enzyme exhibits activity over wider ranges of temperature and pH than its native form, perhaps due to the resistance properties of B. Subtilis spores against adverse conditions.

Positional cloning of the genes responsible for important traits in the silkworm

Toru Shimada[1], Tsuguru Fujii[2], Takaaki Daimon[3], Hiroaki Abe[4], Chikara Hirayama[5], Akio Ohnuma[6], Susumu Katsuma[7]

[1]Graduate School of Agricultural and Life Sciences, University of Tokyo, Japan, [2]Graduate School of Agricultural and Life Sciences, University of Tokyo, Japan, [3]National Institute of Agrobiological Sciences, Japan, [4]Tokyo University of Agriculture and Technology, Japan, [5]National Institute of Agrobiological Sciences, Japan, [6]Institute of Sericulture, Dainippon Silk Foundation, Japan, [7]Graduate School of Agricultural and Life Sciences, Japan

The silkworm, Bombyx mori, shows species-specific morphological, physiological and behavioral characters. Some of them have importance in practical breeding and sericulture. For example, the polyphagous feeding is required for the breeding of the strains that adapt to the artificial diet though the normal strains are monophagous to the mulberry leaves. Also recently the strains that produce green cocoons with specific flavonoids are utilized for special silk fabrics or cosmetic materials. After the accurate genomic information was published in 2008, it becomes easier to find the genes responsible for such traits. There are many 'polyphagous' silkworm mutants that feed non-mulberry plant leaves such as the beet and turnip. Recently, we identified two polyphagous genes, spli (soft and pliable) and Bt (Beet feeder). They were allelic mutations of the same gene, Bmacj6, which encoded a putative transcription factor with a POU-homeodomain. These two mutants manifest the abnormalities not only in larval feeding behavior but also in the pheromone preference in the adult males, suggesting that Bmcj6 play multiple roles in the chemical sensing. It is known that the green cocoon trait is controlled by at least three loci, Ga (Green a), Gb, and Gc. We found that a UDP-glucosyl transferase (UGT) gene is responsible for Gb. The normal silkworms do not show the 5-O-glucosyl transferase activity for quercetin, a mulberry-derived flavonoid. On the other hand, the Gb individuals express the enzymatic activity to produce 5-O-glucosylated quercetin. It indicates that the +Gb locus encodes the quercetin 5-O-glucosyl transferase, unreported in other organisms.

Responses of *Bombyx mori* cells to nucleopolyhedrovirus infection

Michihiro Kobayashi[1], Motoko Ikeda[2]
[1]*Nagoya University, Japan,* [2]*Nagoya University, Japan*

BM-N and BmN-4 cells derived from the silkworm, Bombyx mori, are permissive for B. mori nucleopolyhedrovirus (BmNPV), whereas infection of B. mori cells with other NPVs generally results in various types of abortive infections, providing useful systems for investigating the interactions between NPVs and insect cells. We found that Hyphantria cunea multiple NPV (HycuMNPV) infection of BmN-4 cells results in an abortive infection at the step prior to late gene expression, and that co-infection of BmN-4 cells with BmNPV and HycuMNPV causes restricted BmNPV multiplication, resulting from restricted BmNPV DNA replication and global protein synthesis shutdown of co-infected BmN-4 cells. Analysis demonstrated that HycuMNPV-encoded hycu-ep32 gene is responsible for the restricted BmNPV replication in co-infected BmN-4 cells, showing that the restricted BmNPV replication is rescued in BmN-4 cells co-infected with a hycu-ep32-defective HycuMNPV. Recently, we found that rRNA of BM-N cells undergoes degradation upon infection with various NPVs, including AcMNPV, SeMNPV, HycuMNPV and SpltMNPV. Such rRNA degradation is not observed in other lepidopteran cell lines, Sf9, Ld652Y, Se301 and Splm, suggesting that B. mori has evolved to acquired a unique anti-viral mechanism against NPVs. It was also found that BM-N cells provide advantageous circumstances for BmNPV replication. Our results demonstrated that BmNPV budded viruses cannot be imported into the nucleus of Sf9 and High Five cells which are permissive for AcMNPV, due to lower low-pH-triggered membrane fusion activity of BmNPV GP64, while in BM-N cells, they are successfully migrate into the nucleus through endocytosis and replicate to a high titer.

Identification and regulation of ecdysone response elements (EcREs) in the *Bombyx mori* cathepsin D promoter

Jie Yu[1], Feng-Yao Wu[2], Feng-Ming Zou[3], Jun-Qiang Jia[4], Zhongzheng Gui[5]

[1]Jiangsu University of Science and Technology, China, [2]Jiangsu University of Science and Technology, China, [3]Jiangsu University of Science and Technology, China, [4]Jiangsu University of Science and Technology, China, [5]Jiangsu University of Science and Technology, China

Bombyx mori Cathepsin D (BmCatD) is specifically expressed in the fat body, and plays a critical role for the programmed cell death of the larval fat body and larval gut during metamorphosis. To better understand the transcriptional control of BmCatD expression, this study was conducted to clarify the regulation of ecdysone response elements (EcREs) in the BmCatD promoter with an AcMNPV (autographa californica nucleopolyhedrovirus) vector containing a Dual-Glo Luciferase Assay System. We identified three putative EcREs located at positions ?109 to ?99, ?836 to ?826 and ?856 to ?846 relative to the transcription start site. Analysis of this EcRE region by overlapping deletion studies showed that the three EcREs suppress the ectopic expression of the BmCatD promoter. These results suggest that the EcREs are necessary for activation of the promoter by 20-hydroxyecdysone (20E) in the larval fat body because EcRE mutations lost the fat body-speci?c expression of the BmCatD gene. Our results further support the crucial role of ecdysone signaling to control cathepsin D gene transcription and they suggest that the heterodimeric complex EcR/USP mediates the activation of ecdysone-dependent BmCatD transcription in the larval fat body of B. mori.

Apoptosis-related genes involved in cytoplasmic polyhedrosis virus infection in silkworm, *Bombyx mori*

Kun Gao[1], Ping Wu[2], Xiangyuan Deng[3], Guangxing Qin[4], Ting Liu[5], Heying Qian[6], Xijie Guo[7]

[1]Jiangsu University of Science and Technology, China, [2]Jiangsu University of Science and Technology, China, [3]Jiangsu University of Science and Technology, China, [4]Jiangsu University of Science and Technology, China, [5]Jiangsu University of Science and Technology, China, [6]Jiangsu University of Science and Technology, China, [7]Jiangsu University of Science and Technology, China

Bombyx mori cytoplasmic polyhedrosis virus (BmCPV) is a viral pathogen causing enormous damage to sericultural industry. The molecular mechanism of silkworm response against the virus infection is still obscure. In our resent study, some genes related to apoptosis were found to be probably involved in the virus infection in the silkworm. They are Bombyx mori insulin-related peptide-binding protein2 (BmIBP2), ganglioside-induced differentiation associated protein 1 (BmGDAP1), LIM and SH3 protein 1 (BmLASP1), and Synoviolin (BmSYVN). The polypeptides they encoded possessed respectively conserved domains and motifs, with a signal peptide, an IG and an IGc2 domain in BmIBP2, a thioredoxin-like, a glutathione S-transferase-C (GST-C) and a transmembrane domain in BmGDAP1, a LIM, two nebulin repeats and a SH3 domain in BmLASP1, a HRD1 domain in BmSYVN. BmIBP2 mRNA was only expressed in midgut, while others could be found in all the tissues detected. The level of BmGDAP1 mRNA transcripts was higher in midgut and haemolymph than in other detected tissues. That of BmLASP1 was higher in testicle, ovary, head and spiracle than in midgut, fat body, silk gland, vasa mucosa and hemolymph, with the highest expression level in gonad. All of their mRNA expression levels could be remarkably up-regulated by BmCPV challenge except BmLASP1 whose relative expression level in midgut was down-regulated. Western blotting also revealed that BmIBP2 was expressed in midgut in a tissue-specific manner. Based on the results, it is speculated that these genes including BmGDAP1, BmIBP2, BmLASP1 and BmSYVN might be involved in apoptosis immune response against BmCPV infection.

Molecular and enzymatic characterization of two tetrahydrobiopterin synthesis-related enzymes of the silkworm *Bombyx mori*

Yan Meng[1], Junshan Gao[2], Wenjing Wang[3], Jing Wang[4], Chaoliang Liu[5], Toru Shimada[6]

[1]Anhui Agricultural University, China, [2]Anhui Agricultural University, China, [3]Anhui Agricultural University, China, [4]Anhui Agricultural University, China, [5]Anhui Agricultural University, China, [6]The University of Tokyo, Japan

Tetrahydrobiopterin (BH4) plays important role in the production of monoamine neurotransmitters as a cofactor for aromatic amino acid hydroxylases. BH4 deficiency has been associated with many neuropsychological disorders. Oral administration of BH4 has shown improvement for some BH4 deficiency-dependent diseases in human. However, commercial BH4 produced by chemical synthesis pathway are very expensive. Two enzymes are needed in the salvage pathway of BH4 synthesis from sepiapterin (SP), one is SP reductase (SPR) and the other is dihydrofolate reductase (DHFR) in vivo in mammals. SP is a major pigment component contained in the integument of lemon (lem), a silkworm Bombyx mori mutant strain in high concentration, suggesting lem is an invaluable biological resource to extract natural SP. Based on the newly integrated B. mori WGS database and EST libraries, we cloned and identified two genes encoding B. mori SPR (BmSpr) and DHFR (BmDhfr), respectively. Recombinant proteins were expressed using a prokaryotic expression system and their enzymatic properties were analyzed. The results showed that both BmSPR and BmDHFR exhibited high catalytic activity and suitable parameters to substrate. In addition, we have established an effective experimental system to isolate and purify SP from lem silkworms. Together, it is possible and of great significance that SP could be industrially extracted in large scale to bio-pharmaceutically produce BH4 in vitro by co-expressing BmSPR and BmDHFR and using the natural SP as a substrate in the future.

Utilization of the *Bombyx mori* heat shock protein 70 promoter for efficient transgene expression

Tae-Won Goo
National Academy of Agricultural Science, Republic of Korea

For stable germline transformation of Bomyx mori, the promoter of the Bombyx cytoplasmic actin 3 (BmA3) was used to choose to drive the EGFP in piggyBac vector. The BmA3-EGFP marker was found to be useful for the screening of G1 transgenic individuals at the larval stage, but not detectable in embryonic stages. To identify more powerful promoter than previously reported BmA3 promoter, we isolated 9 clones that show stronger signal compared to BmA3 by dot blot hybridization. Among these 9 clones, we focused on one clone which has high amino acid homology (94%) with hsp70 gene of Trichoplusia ni. This clone, named bHsp70 was ubiquitously expressed in all tissues and developmental stage of B. mori, and up-regulated by thermal and ER stress. As result of promoter assay using dual luciferase assay system, we found the highest transcription activity region (-1003/+147) in the 5'-flanking region of bHsp70 gene, which has about 264 fold more intensive promoter activity than BmA3 promoter. Transcriptional activity of bHsp70 promoter under heat shock condition (42℃, 4 hr) was increased over 2 fold than normal condition. Moreover, the bHsp70-EGFP marker was detected ubiquitously in embryonic, larval, pupal, and adult tissues of transgenic silkworm. Therefore, it is possible to screen transgenic individuals before the G1 larval stage using this promoter, because the bHsp70-EGFP marker was expressed in embryos. As above results, we suggest that bHsp70 promoter may be used more effectively for the large-scale production of biologically active recombinant proteins and screening of transgenic silkworm.

Identification of immune-related genes from the japanese oak silkworm, *Anthereae yamami*

Seong-Ryul Kim[1], Seung Won Park[2], Kwang Ho Choi[3], Tae Won Goo[4], Seok Woo Kang[5]

[1]National Academy of Agricultural Science, Republic of Korea, [2]National Academy of Agricultural Science, Republic of Korea, [3]National Academy of Agricultural Science, Republic of Korea, [4]National Academy of Agricultural Science, Republic of Korea, [5]National Academy of Agricultural Science, Republic of Korea

The main targets of our investigation were innate immunity-related genes and effector moleculeS, the key components of humoral defense reaction in the japanese oak silkworm, Anthereae yamami. The expressed sequence tag (EST) analysis was used for screening of genes that are induced to injected bacterial lipopolysaccharide (LPS). Analysis of 1120 cDNAs resulted in identification of 22 novel immune-related genes including pathogen recognition, modulation and putative antimicrobial peptides. In addition, we compared acidic extracted hemolymph protein profiles between control and immune-challenged A. yamami larvae using two-dimensional gel electrophoresis (2-DE). Protein spots showing differential expression were identified by MALDI-TOF and MS/MS spectra. Subsequently, two of them were estimated to be attacin antibacterial peptides with high coverage of sequence. These attacin peptides were intensively induced after an immune-challenge with LPS.

Keywords:*Immune-related gene, antimicrobal peptide, Anthereae yamami, cDNA, attacin*

Role of *Bombyx mori* prophenoloxidase-activating factor in pupal melanization

Kwang Sik Lee[1], Feng Ming Zou[2], Bo Yeon Kim[3], Byung Rae Jin[4]

[1]Dong-A University, Republic of Korea, [2]Dong-A University, Republic of Korea, [3]Dong-A University, Republic of Korea, [4]Dong-A University, Republic of Korea

In arthropods, an immune challenge triggers a serine protease cascade that leads to the activation of prophenoloxidase (proPO)-activating factors (PPAFs), which are also called proPO-activating enzymes (PPAEs) or proteinases (PAPs). PPAFs are activated by cleavage between their clip and serine protease domains. Once activated, PPAFs convert proPO to phenoloxidase (PO), which then catalyzes the production of quinones to form melanin. In this study, we identified a Bombyx mori PPAF (BmPPAF) that involves in the pupal melanization. In the fat body, expression of BmPPAF was detected on day 1 to 3 of the pupal stage. RNA interference (RNAi)-mediated BmPPAF knock-down inhibited pupal melanization, resulting in the delay of pupal melanization. Based on these results, we concluded that BmPPAF is involved in the melanization of pupal stage in silkworm metamorphosis.

Structural fundamentals of silk protein biopolymer and biomedical applications of silk nanofibrous scaffolds

Young Hwan Park[1], Chang Seok Ki[2], Jong Bo Park[3], Hyun Jung Kim[4]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Seoul National University, Republic of Korea, [4]Seoul National University, Republic of Korea

Silk protein has been great interests to materials scientists in biomedical application fields recently because it has excellent processibilities, physical properties and biocompatibility. Many studies and trials are needed to determine the nature of silk structure and mechanism of silk fiber formation in nature. With the progress of tissue engineering technology, tissue engineering scaffolds and implants of silk based biomaterials are paticularly attractive in various forms and silk protein can be a one of very important candidates for biomedical polymers. In the case of silk scaffolds, we demonstrate that highly porous electrospun 3D silk nanofibers can offer exceptional functionalities and benefits over conventional synthetic and natural biopolymers in generating tissue replacement for various cells and organs, specially in the fields of bone and nerve regeneration.

New biomonitring guidelines using river benthic macroinvertebrates in Japan

Kazumi Tanida[1], Takao Nozaki[2], Kimio Hirabayashi[3], Koji Tojo[4]

[1]Osaka Prefecture University, Japan, [2]Society of Biology of Inland Waters, Japan, [3]Shinshu University, Japan, [4]Shinshu University, Japan

For these 3 years, we are discussing the new guidelines of riverine biomonitoring using macroinvertebrates in a committee of Ministry of Environment, Japan. We are now getting the final version of guidelines. We will introduce these ones for elementary and advanced types of biomonitoring. The former is a nation-wide biomonitoring for students and citizens, which can designate four classes of water quality using 33 riverine animals. Another one is average score method (ASPT-J: average score per taxon) similar to the score proposed by BMWP (Biological Monitoring Working Party in England), which will be used by local institutions, university researchers and students. For the advanced type of biomonitoring, we designated the scores (1 to 10) for 72 families of aquatic insects and other macroinvertebrates. We compared ASPT-J scores and chemical or biochemical (BOD) water quality values using the nation-wide river organism census in Japanese major rivers and streams, and obtained the reference (unpolluted sites) score of ASPT in Japan.

Keywords:*guideline, average score per taxon, reference score,census*

Change in life history traits of a water strider, *Aquarius paludum* during 1995-2011 in accordance with global warming

Tetsuo Harada[1], Tomoya Furutani[2], Takashi Shiraki[3], Shiho Takenaka[4], Shinya Maihara[5], Toshiki Tamura[6], Shuichi Nitta[7], Ken Ito[8], Kazufumi Doi[9]

[1]Kochi University, Japan, [2]Kochi University, Japan, [3]Kochi University, Japan, [4]Kochi University, Japan, [5]Kochi University, Japan, [6]Kochi University, Japan, [7]Kochi University, Japan, [8]Kochi University, Japan, [9]Kochi University, Japan

Seasonal records of the last instar nymphs of the water strider, Aquarius paladum in a waterway in Kochi prefecture, Japan (33°00'N to 33°30'N) in 2010 show that populations of new generation adults occur five or more times during the year, from May to December, whereas only three new ones occurred there in 1995. In laboratory experiments, more than 50% of adults are reproductive irrespective of photoperiod. There is a diminishing photoperiodic response in 2007 in relation to induction of diapause when compared to measurements made in previous years (1995-97), suggesting that reproduction may be possible over a much longer period, possibly even in winter, in the near future. In summer of 2008, 2010 and 2011, a high proportion of males sampled had small testes and 60-70% of females had no mature oocytes. This contrasts with earlier summer data, which shows that the testes volume was larger in 1995-1997, and that 75% of females had mature oocytes. These changes may suggest that this population of A. paludum shows partial aestivation. More than 70% of overwintering adults of both sexes are found to have no mature flight muscles in October-November of 2008-2011. A new mosaic-typed wing morph (long fore-wings and short hind-wings) occupied 20% of the overwintering population in 2010. This contrasts with previous observations in 1995 and 2004. The absence of mature flight muscles and the mosaic wing morph in the autumn may be evidence of cessation of dispersal between the summer habitats and overwintering sites on land far from

The responses and predicted distributions of benthic insects (Ephemeroptera, Odonata, Plecoptera, Coleoptera, and Trichoptera) to global warming: A multivariate study in Korea

Fengqing Li[1], Yong-Su Kwon[2], Mi-Jung Bae[3], Namil Chung[4], Young-Seuk Park[5]

[1]Kyung Hee University, Republic of Korea, [2]Kyung Hee University, Republic of Korea, [3]Kyung Hee University, Republic of Korea, [4]Kyung Hee University, Republic of Korea, [5]Kyung Hee University, Republic of Korea

Peninsular environments are one of the ecosystems most vulnerable to global warming. Despite the importance for the conservation of regional biodiversity, they are among the environments least studied with respect to the influences of global warming. In this study, we used benthic macroinvertebrate community data collected on the Korean nationwide scale, to evaluate the potential impact a temperature increase on river ecosystems. Weighted averaging regression models were used to project the relationships between relative benthic insects abundance and water temperature, based on the temperature data of the Intergovernmental Panel on Climate Change (IPCC) A1B scenario. Stoneflies were identified as potentially the most sensitive taxa to global warming, whereas the dragonflies and beetles were benefited from the global warming. The impact of warming on macroinvertebrates was predicted to be minimal prior to the 2060s; however, by the 2080s, species loss of up to 46% was predicted at the highland areas, whereas 11% was predicted at the lowland areas. Potential distribution ranges of cold water species (Plecopteran Sweltsa nikkoensis) in the future decades were expected to decrease continuously over time, while those of warm species (Odonatan Ischnura Asiatica and Coleopteran Psephenoides sp.) were expected to increase from the 2000s to the 2040s and to then decrease until the 2080s. Our projections may be useful for understanding how climate parameters affect the biogeographical patterns of aquatic biodiversity from a thermal-preference perspective.

The current status of Australian Ephemeroptera

Kyla Jane Finlay
Department of Primary Industries Victoria Australia, Australia

Knowledge of Australian Ephemeroptera is poorly known despite a relative proliferation of work in the last 10-15 years or so. Deficiencies in taxonomic knowledge of the largely endemic fauna have hindered ecological studies particularly the use of mayflies as bioindicators. At present there are over 100 described species with estimations of at least twice that number of species to be described. Further there are presently few researchers working on mayflies, and mayfly taxonomy in particular, in the country. This paper will present the current status and knowledge of Australian mayfly research.

Current status of freshwater macroinvertebrates in Korea

Yeon Jae Bae[1], Sang Woo Jung[2]
[1]Korea University, Republic of Korea, [2]Korea University, Republic of Korea

The available literature on the status of Korean freshwater invertebrates was reviewed. Early descriptive and faunistic studies before the 1960s were conducted by Martens (1883-1884) for Mollusca, by Imanish (1940) for Ephemeroptera, and by Cho (1946) for Hemiptera. During the 1960s?1970s, faunistic studies, standing crop comparisons, community studies for water quality assessment, and taxonomic studies on diverse groups of freshwater macroinvertebrates were initiated. Kim (1974) comprehensively studied Korean Trichoptera larvae. During the 1980s?1990s, intensive taxonomic studies of aquatic insects resulted in a monograph (Yoon, 1988) that included 387 species and a key book (Yoon, 1995) that included 340 species. Bae and Yoon (1999) compiled checklist of 638 species of freshwater benthic macroinvertebrates including 491 species of aquatic insects. Since the 1980s, nation-wide government projects such as "National Ecosystems Survey (1986?current: Ministry of Environment, MOE)," "KLTER (2004?current: MOE)," "Korean Native Species Survey (2007?current: NIBR)," "Korean Fora and Fauna Project (2007?current: NIBR), and diverse conservation, restoration, and education programs largely supported the research on freshwater macroinvertebrates in the country. Currently, 1,283 species of freshwater macroinvertebrates including 988 aquatic insects, have been identified in Korea: Cnidaria (1 sp.), Plathyhelminthes (3 spp.), Nematomorpha (8 spp.), Bryozoa (11 spp.), Mollusca (63 spp.), Annelida (52 spp.), Crustacea (42 spp.), Aranea (1 sp.), Ephemeropetra (81 spp.), Odonata (117 spp.), Plecoptera (102 spp.), Hemiptera (83 spp.), Megaloptera (4 spp.), Coleoptera (131 spp.), Hymenoptera (1 sp.), Diptera (334 spp.), Trichoptera (236 spp.), and Lepidoptera (13 spp.).

Comparative study on tolerance to sea, brackish and fresh water bodies as habitat in oceanic sea skater of *Halobates micans* and fresh water Halobatinae species *Metrocoris histrio* (Heteroptera)

Takero Sekimoto[1], Koki Iyota[2], Yuki Osumi[3], Takashi Shiraki[4], Tetsuo Harada[5]

[1]Kochi University, Japan, [2]Kochi University, Japan, [3]Kochi University, Japan, [4]Kochi University, Japan, [5]Kochi University, Japan

Experimental adult specimens ofoceanic sea skater, Halobates micanswere placed in one of 4 salinity conditions [sea water(35-36% salinity), sea water : fresh water = 2:1(23-24%), sea water : fresh water = 1:2(11-13%), fresh water(0%)]8 hours ? 10 days aftercollection from the tropical Indian Ocean (04º09'S, 094º26'E to 10º39'S, 079º18'E). The specimens were checked to see if they were alive without food every 2 hourscontinuously until all adults had died. Paralysis from fresh water shock occurred within 2-9hrs in all specimens after which they died within 2 hours. Significantly longer survival without food was observed in both species on 1/3 and2/3 sea water than on regular sea water. The longer survivalby oceanic sea skaters onbrackish waters may be an adaptation to occasional rain fall on the sea water film.The threshold value for behavioral paralysis to occur due to lower salinity was 9% for H. micans.The average hours of survival of a brackish water species, Metrocoris histrio were 78h, 44h, 11h, 6.5h and 3.5h on 0%, 5%, 10%, 12.5% and 15% salinity water, respectively. Low resistance of this fresh water species to salinity may be related to the lack of experience with brackish water from ecological and evolutionary points of view, while relatively high resistance to lower salinity water by ocean sea skaters may be an adaptation to rainfall on the ocean surface.

Directional movement of aquatic insects in larval and adult stages in streams based on individual based models

Tuyen Van Nguyen[1], Rupert Mazzucco[2], Dong-Hwan Kim[3], Ulf Dieckmann[4], Tae-Soo Chon[5]

[1]Pusan National University, Republic of Korea, [2]International Institute of Applied Systems Analysis, Austria, [3]Pusan National University, Republic of Korea, [4]International Institute of Applied Systems Analysis, Austria, [5]Pusan National University, Republic of Korea

An eco-evolutionary individual-based model (IBM) was developed to accommodate life events of aquatic insects including birth, death, diffusion, and drifting under various biological (e.g., local competition) and environmental (e.g., unidirectional flow) constraints. Evolution of the heritable traits was simulated regarding adapted water velocity, drifting tendency, and upward flight distance by adults. Evolutionary branching in the adapted velocity trait was accordingly addressed as the time progresses, and spatial distribution of assemblages was also presented in riffles and pools. Directional movement such as larval drifting contributed to population maintenance in stream conditions. Upstream flight by adults was also observed to play a key role in adaptive dynamics of insect communities, resolving drift paradox in insect communities in streams. The feasibility of IBM was further discussed regarding monitoring of natural and anthropogenic disturbances under biological and environmental constraints.

Biological and genetic aspects of the non-biting midge Glyptotendipes tokunagai Sasa (Diptera: Chironomidae) during 30 generations of rearing under laboratory conditions

Min Jeong Baek[1], Tae Joong Yoon[2], Jeong Mi Hwang[3], Yeon Jae Bae[4]

[1]Korea University, Republic of Korea, [2]Korea University, Republic of Korea, [3]Korea University, Republic of Korea, [4]Korea University, Republic of Korea

The non-biting midge Chironomidae has been used worldwide as a water quality indicator and toxicity test organism. This study was conducted to establish a new toxicity test organism by using the chironomid Glyptotendipes tokunagai Sasa, which is widespread in Northeast Asia. Four egg masses of G. tokunagai were collected from the Jungrang Stream in Seoul in April 2007 and were successively reared in the laboratory for over 33 generations in the last 5 years. The number of eggs in an egg mass, hatching rate, and adult body sizes of G. tokunagai were monitored. Genetic analysis was also performed using the partial mitochondrial DNA cytochrome c oxidase I (COI) gene. The influence of temperatures ranging from 8°C to 42°C on development rate was also examined. The number of eggs in an egg mass was shown to rapidly decrease in the early generations, and then it stabilized after the fourth generation ($p < 0.05$). All the examined generations showed a mean hatching rate greater than 75%. Adult body size of the midges was significantly reduced in the initial 3 generations, and then it stabilized in the following generations ($p < 0.05$). The genetic diversity of the reared generations was shown to decrease from 0.004898 to 0.000386. The optimal rearing temperature for G. tokunagai was shown to be within the range of 25?30°C. This is the first case of chironomid domestication in Korea, where the non-biting midge has been successfully reared for at least 5 years under laboratory conditions.

Species abundance distribution of benthic *Macroinvertebrate* communities under stressful and recovering conditions in the streams

Woon-Seok Cho[1], Dong-Hwan Kim[2], Young-Seuk Park[3], Hungsoo Kim[4], Tae-Soo Chon[5]

[1]Pusan National University, Republic of Korea, [2]Pusan National University, Republic of Korea, [3]Kyung Hee University, Republic of Korea, [4]Pusan National University, Republic of Korea, [5]Pusan National University, Republic of Korea

Benthic macroinvertebrates were monthly collected at 11 sampling sites of the Yangjae Stream, Han River, for three years. Community responses to pollution and recovery were analyzed using species abundance distribution (SAD). The SAD models (e.g., geometric series, log series, and lognormal distribution) reflected pollution impact accordingly. The SADs generally showed geometric series in polluted states, and changed to lognormal distribution as the stream recovered. Variability in community structure was also associated with changes in biological indices (e.g., ASTP, diversity and EPT) and environmental factors (e.g., DO, BOD, conductivity, and pH). The SADs of benthic macroinvertebrate community effectively reflected aquatic ecosystem integrity and could be suitable in monitoring stream communities in stress and recovery.

Local ecological knowledge of the weaver ant *Oecophylla smaragdina*, used as human food, from Vientiane Municipality, Lao PDR

Joost Van Itterbeeck[1], Niane Sivongxay[2], Bounthob Praxaysombath[3], Arnold Van Huis[4]

[1]Wageningen University, Netherlands, [2]National University of Laos, Lao People's Democratic Republic, [3]National University of Laos, Lao People's Democratic Republic, [4]Wageningen University, Netherlands

A large variety of insect species is used as human food in the Lao PDR. The brood (eggs, larvae, and pupae) of the Asian weaver ant Oecophylla smaragdina (Fabricius), in particular the larvae and pupae of the queen caste, is one of the most popular. The recording of local ecological knowledge of edible insects has so far received little attention. We conducted focus group discussions and participant observations with expert collectors in three rural villages in Xaythani District, Vientiane Municipality, Lao PDR. Our discussions were concentrated on O. smaragdina reproduction, castes, developmental stages, behaviour, nest characteristics and their contents, host trees, and on harvesting methodologies and their effect on the ants. Peoples' local ecological knowledge is partly compatible with the scientific literature on O. smaragdina biology and ecology. Misinterpretations on weaver ant biology and ecology primarily occur due to lack of knowledge on (1) ant behaviour inside undisturbed nests, (2) the role of reproductive forms, and (3) the antagonistic behaviour between O. smaragdina colonies.

Insects - Source of biologically active substances in contemporary pharmacology

Mircea Ciuhrii
Insect Farm, Romania

Authors: CIUHRII MIRCEA, MONICA POPESCU Insects, unlike other organisms through various stages of development: egg, larva, pupa and adult. Different chemical composition in each phase. The egg and larva prevails biologically active substances and the transformation of larval stages in pupae and pupae in imago, predominant inhibitory substances (Ciuhrii, 2005,2009, 2010,2011,2012), which served to obtain natural interferon's and cytostatics (06/06/2000 N B. 20605,2011,118115 Ciuhrii patent OSIM) to stop viral infections and tumors. In the near future, insects will cause a revolution in the pharmaceutical industry (Ciuhrii, 2011). In future insects become food sources for humans (Ciuhrii, patent 2011, NA 00963 OSIM Romania). We developed several treatment technologies most dangerous viral diseases and tumors, which in future will allow increased longevity.

Status of resources insects research and industrialization in China

Xiaoming Chen[1], Ying Feng[2]
[1]*Chinese Academy of Forestry, China,* [2]*The Research Institute of Resources Insects, Chinese Academy of Forestry, China*

Insects are the biggest biological resource on the earth, which have still not been exploited fully. China has more than 5000 years history of utilization of insect resources, for example, silkworm rearing, bee-keeping. In China, insect as resource utilization and commercialization develop rapidly in recent year, resources insects become a special subject in China. Resource insects refer to the insect products or insect body itself or insect behavior have special values or can be directly or indirectly used as resources by humans. Resource insects have economic, ecological and scientific value, deal with insect as industrial raw material, such as, lac insect(shellac), white wax scale insect(insect wax), gallic aphids(tannic acid products), cochineal(pigment), silkworm, honeybee, insect as protein(edible insects), insect as medicine, ornamental insects(butterfly), insects as natural enemies of pests, pollination insects, and the insect cell engineering and so on. Their value is more than 100,000 million. Many research results are constantly emerging, and numerous achievements in scientific research have been put into use. For example, shellac, the secretion of lac insect, has been used as food coatings. 177 species of edible insects were recorded in China and a lot of edible insects are going to restaurant. More than 200 species of medicinal insects were recorded and some of them have being studied for modern pharmacology. And more than 40 species butterflies have reared artificially for butterfly garden and crafts. These insects will provide rich new sources for chemical industry, food, protein products, health care products and medicine.

Application of butterfly and moth wing patterns on the fabrics? An entrapreunurial approach

Ezhili Nil Nagarajan
PSGR.Krishnammal College for Women, India

Butterflies and Moths are natural beauties and appear in famous paintings dating back to the days of our cave-dwelling ancestors.They were also focal points in the delicate silk screens of early Chinese and Japanese artists.Butterflies and moths belong to the Order Lepidoptera are covered with thousands of tiny overlapping scales.The prior art does not describe any methodology to obtain this brilliant coloring effects and the patterns displayed by the insects such as butterflies and moths.The basic design was obtained from the good quality digital photos of butterflies and moths.The photographs taken under natural light was used to develop the designs.Preferably high resolution photos of 3456x2596 dimension digital photos were used.The selected butterfly photos were edited using Photoshop to select a portion of the wing design.The selected insect wing design was placed in Page Maker and Corel draw to make designs.Multiple copies of the insect wing design were generated to get full view of the design. It was inferred that multiple designs can be developed from a single species. There is a need for a providing cost effective design and pattern for the textile industry that are very natural with brilliant coloring effect thereby reducing cost and time factor for producing patterns and designs and the present invention provides the same. In the present study the methodology of making designs using wing pattern of moths and butterflies has been tried. An attempt has been made to print those generated designs on fabric.

Utilization of edible insects in China

Ying Feng[1], Xiaoming Chen[2], Min Zhao[3]
[1]Chinese Academy of Forestry, China, [2]Chinese Academy of Forestry, China, [3]Chinese Academy of Forestry, China

Edible insects have been used as a food source for more than three thousand years in China. Recently published articles have suggested that there are more than 200 species of edible insects in China. Edible insects are rich in protein and amino acids, especially eight essential amino acids, which makes them an excellent source of protein. Apart from a good source of protein, edible insects can also provide fat, fatty acids, vitamins and carbohydrates. Edible insects are usually sold in open markets directly as a seasonal and delicious food item in China. Local people believe that edible insects are nutritious and pollution-free food since insects are captured from the wild. Although people increasingly realize the importance of edible insects and gradually accept edible insects as a food source, there are not many products made from edible insects in China. But some researchers and producers have tried to make insect products. Not many of edible insects were evaluated for food safety although researchers developing insect food products understand the significance of food safety and have proposed to develop evaluation procedures. There is no specific law regulating edible insects in term of trading and rearing in China. But there still are some other laws and regulations for animals and plants which may apply to edible insects. If we want to develop edible insects as one food source, some research and practice are necessary. Those are edible insect species identification, large scale rearing, insect food products and insect safety evaluation as food source.

Assuring food security by using insects as food and feed

Arnold Van Huis
Wageningen University, Netherlands

By 2050, the world will need between 70 and 80% more meat to feed a 9.1 billion population of increasingly demanding consumers. With the amount of available agricultural land being constrained, the production of sufficient protein from livestock, poultry and fish represents a serious challenge for the future. More than 2000 species of insects are eaten worldwide, mainly in developing countries. However, if no action is undertaken this food habit will soon disappear. Edible insects constitute high quality food for humans and feed for livestock, poultry and fish. They are cold blooded and therefore have high food conversion rates. They emit less greenhouse gases and ammonia than conventional livestock. Some insect species can be grown on organic side streams reducing environmental contamination, and transforming waste into high protein feed that can replace increasingly expensive compound feed ingredients such as fish meal, fish oil and soybean. Therefore, edible insects are a serious alternative for conventional production of other animal based protein sources, either for direct human consumption, or indirectly as feedstock. This requires the development of cost-effective automated mass rearing facilities providing a reliable, stable and safe product. In the tropics, sustainable harvesting needs to be assured and rearing practices promoted, while in general the food resource need to be revalorized. In the western world, consumer acceptance can be enhanced by developing processing technologies of insect-derived protein products recipes. The appropriate regulatory framework for allowing insects as food and feed needs serious attention.

Structure and properties of silk from African wild silkmoths

Addis Teshome Kebede[1], Suresh Kumar Raina[2], Fritz Vollrath[3]

[1]International Center of Insect Ecology and Physiology, Kenya, [2]International Center of Insect Ecology and Physiology, Kenya, [3]University of Oxford, United Kingdom

The African wild silkmoths produce commercially important silk and are found distributed along wide range of ecologies in Africa. Variations between silks of four silkmoths; Argema mimosae, Anaphe panda, Gonometa postica and Epiphora bauhiniae, were studied regarding their structure, mechanical and thermal degradation properties using SEM, FTIR, tensile testing and TGA. The wild cocoon shells and fibers showed remarkable differences in surface and cross sectional structures. G. postica and A. panda had thorny spines and hairs on their cocoon surface, while A. mimosae cocoons were highly perforated. Cocoon surfaces had cross bindings, wrinkles and networking of twisting filaments. The FTIR spectra proved the presence of calcium oxalate crystals on G. postica and E. bauhiniae cocoon shells. G. postica and A. mimosae cocoon shells had lower breaking stress and breaking energy than B. mori. G. postica fibers had the highest breaking strain (41.3 %) and the lowest breaking stress (237 MPa). B. mori had the highest breaking stress than the wild silk fibers (427.6 MPa). The TGA curves showed fibers of G. postica and cocoon shells of A. mimosae lost the highest weight due to dehydration (13.3 and 11.9 %, respectively). Total weight losses for degummed fibers and cocoon shells were highest for B. mori and E. bauhiniae (93.4 and 97.2, respectively). The study revealed existing variability in structure and properties among the African wild silk fibers that could be attributed to selection for adaptation and difference in molecular organization and chemical composition of silk spun by each species.

Insect biodiversity and humanity

Ke Chung Kim
Pennsylvania State University, U.S.A

Insects are not antagonists but partners to humanity. Today's insects and their cohorts are prominent taxa of long evolutionary history that have been here on the planet long before human species emerged and evolved into "technological being" for the last century. Today's world with over 7 billion people is quite different in many ways under the threat of biodiversity loss and global warming and its climate change from what it was 50 plus years ago which was 3 billion. At this juncture, we no longer can afford to look at insects solely from anthropocentric perspective, as insects explore and settle in new habitats that we create in the context of development for humanity. To develop new application we need to change our approach to studying the biology of insects not as pests or antagonists but as ecological partners in biodiversity, at any spatially defined site which should go a long way for science. Insect biodiversity refers to the totality of everything about the insects on the planet which our knowledge base is rather incomplete and scanty as yet. We must advance our research on diverse aspects of insect biodiversity in order to expand the application and development of insects for humanity which help to advance sustainability of insects and their cohorts whereas human sustainability may be warranted for perpetuity.

Arazyme and highly active enzymes developed by microbes from insects in Korea

Ho-Yong Park
Korea Research Institute of Bioscience and Biotechnology, Republic of Korea

Arazyme, a highly active protease was developed by the microbe isolated from the spider, Nephilaclavata in Korea. Arazyme has high enzyme activityrelatively in the wide range of temperature, pH, substrates, and salt concentration. Arazyme has also natural antibiotic and anti-inflammatory activities. Arazyme is using commercially inthe field of food, animal feed, cosmetics, life cares, laundry detergent, leather processing, and pharmaceuticals. Other highly active enzymes, such as xylanase, mannanase and lipase, were developed from the beetle etc. These enzymes are using especially for animal feed to increase digestion rate and to prevent diseases of animal. And these enzymes are also using for biofuel production industry.Insect Biotech is the leading company which has commercialized the highly active enzymes from insects in diverse industries.

International entomology

Thomas Albert Miller
Entomology, University of California, Riverside, U.S.A.

The USA recently celebrated the 150th anniversary of the Morrill Act considered by many to be one of the most successful laws ever passed. It established the land grant universities making higher education available to everyone. It was followed by the Hatch act a few years later that established the Agricultural Experiment Stations in the USA. These two events opened up new fields, but expanded the search for science and technology as underlying innovation. Many generations of students from abroad benefitted from training in these centers. Some stayed to become faculty members and others returned to their countries of origin to create a science based support for agricultural research. It is this network of scientists who form the backbone of international entomology. The tools available for dealing with crop pests and diseases can be counted on the fingers of one hand. This leaves few choices when faced with new threats. Modern application of genetically modified crops and insects have come under unprecedented scrutiny. Resulting in new tools being blocked or abandoned. It is difficult to explain why this has happened, but that reality will not go away. The two main examples beyond transgenic plants are transgenic insects and symbiotic control of crop pests and diseases. These examples and the reasons for preventing approval will be discussed.

Molecular mechanism and application of coprisin, defensin-like peptide, from copris tripartitus

Jae-Sam Hwang[1], Eun-Young Yun[2], Joon-Ha Lee[3], Ho Kim[4], Dong Gun Lee[5]

[1]National Academy of Agricultural Science, RDA, Republic of Korea, [2]National Academy of Agricultural Science, RDA, Republic of Korea, [3]National Academy of Agricultural Science, RDA, [4]Daejin University, Republic of Korea, [5]Kyungpook National University, Republic of Korea

We report the isolation and characterization of a novel defensin-like peptide from the dung-beetle Copris tripartitus. A cDNA encoding an 80-mer defensin-like propeptide was identified and its predicted molecular mass and pI were 8.6 kDa and 8.7, respectively. A 43-mer mature peptide was also selected and named herein as Coprisin. We also investigated active sequences of Coprisin by using amino acid modification. The antimicrobial activity of chemically synthesized coprisin against human bacterial pathogens was subsequently investigated. Coprisin exerted antifungal and fungicidal activity without any hemolytic effect. Confocal microscopy indicated that coprisin accumulated in the nucleus of cells. The membrane studies, 1,6-diphenyl-1,3,5-hexatriene, calcein-leakage, and giant unilamellar vesicle assays, confirmed that coprisin did not disrupt the fungal plasma membrane at all. And we examined whether treatment with a coprisin analogue (a disulfide dimer of the nine peptides) prevented inflammation and mucosal damage in a mouse model of acute gut inflammation established by administration of antibiotics followed by C. difficile infection. In this model, coprisin treatment significantly ameliorated body weight decreases, improved the survival rate, and decreased mucosal damage and proinflammatory cytokine production.
A coprisin analogue peptide selectively caused a marked decrease in cell viability in Jurkat T, U937, and AML-2 cells (human leukemia cells), but was not cytotoxic to Caki or Hela cells. Fragmentation of DNA, a marker of apoptosis, was also confirmed in the leukemia cell lines, but not in the other cells. In conclusion, our results demonstrate coprisin as a potential therapeutic agent, possibly can be replaced traditional antibiotics to overcome antibiotic resistance.

Clarifying Initiatives for Retaining Women Entomologists in Academia

Sharron S. Quisenberry
Vice President for Research and Economic Development, Iowa State University, Ames, Iowa 50011

A recent survey of Entomology Departments in the U.S. from 2007-2010 showed that the number of female Ph.D. students increased from 253 to 265 (43 to 48%), and the number of male Ph.D. students decreased from 342 to 386. During that same time, the number of female faculty members increased from 95 to 104 (from 17 to 18%), and the number of male faculty members decreased from 476 to 464. The number of female Assistant Professors decreased (29 to 22%); Associate Professors increased (28 to 31%); and Professors increased (8 to 12%). Twelve causes for concern identified in a 2011 American Physical Society study will be discussed. It is critical to establish an environment and culture that empowers women and men to succeed in academia, and goes beyond bias and barriers. A Call to Action is proposed, focusing on the campus framework for monitoring progress, analysis and utilization of data for organization change, and commitment to take corrective action.

Family and scientific career

Silvia Dorn
ETH Zurich, Switzerland

Combining family and scientific career remains a challenge for women scientists. I will outline how family and career simultaneously evolved in my case. Helpful perspectives include awareness of the different durations of the time periods that are associated with major obligations for career, marriage and family. They also include awareness of choices for one, two or all three of these options, and their respective consequences. Combining all three options means that time becomes one of the most valuable resources in the life of the woman concerned. Setting priorities accordingly might require one, for example, to renounce some hobbies. Organization of private life and useful approaches will be discussed, as well as unexpected reactions from the professional environment. Mastering the combination of professional life and family is a sign of strength, but others may perceive it as a mere risk. Overcoming such prejudices takes time and energy. Leaving the isolation to obtain support and inspiration from other women scientists is a promising step to take. Opportunities for improvements at the institutional and global level will be addressed. They include spontaneous networks and formalized associations. Further, recognition of great achievements of women scientists is a positive signal that is understood globally. Invited submission: Women in Entomology ? Challenges and Achievements in a New Era (19-1.)

Taking the "Men" out of "Mentoring"

Ernest S. Delfosse
Michigan State University, U.S.A.

Effective mentoring is a difficult, learned skill; cross-gender mentoring can be even more challenging. Men are often placed in the position of mentoring women, but do not always understand what needs to be done or exactly how to do it; the same can be said for men mentoring men, women mentoring women, or women mentoring men.Cross-gender mentoring works best when in a safe mentoring environment for mentor and mentee, coupled with an understanding of what is needed during the period of mentoring, and taking into account cultural and gender differences. Cultural and gender assumptions may inadvertently affect the success and perception of mentoring. Basically, the role of a mentor is to provide or transfer something of value to the mentee at a critical time in the mentee's career development. In this presentation, I will discuss these issues from the perspective of a man who has mentored women in academia and government.

ICE 2008 - A glimpse of the inside story

Shirley Hanrahan
University of the Witwatersrand, South Africa

I hope to share the feeling of the roller coaster experience of committing to an undertaking like ICE2008. This talk explores some of the behind the scenes activities, responsibilities and organization needed for a successful international entomology congress. These are completely invisible to the average congress delegate. It will deal with aspects of the pre-bid preliminaries, bid funding, congress funding and financial management. Communications, both with the large number of entomologists who contribute to the congress organization and scientific programme and at a smaller scale the executive committee, play a vital role in making things function smoothly. How this was done? Choosing a professional congress organizer company that is experienced, knowledgeable and professional, but most important of all compatible with the aims and focus of the congress, is vital. This talk also serves as a tribute to a small entomological society that backed their first woman president to the hilt to make this venture a success.

Lessons from symbiotic theory for navigating, surviving, and succeeding in an academic career in entomology

Diana L. Six
University of Montana, U.S.A.

Symbiosis denotes close interactions between organisms of different taxa. These interactions can be categorized as neutralism, commensalism, mutualism, antagonism, or parasitism depending upon outcomes, which in turn, may be context dependent. As an entomologist with a passion for studying symbioses between insects and microorganisms, I have often been struck by the parallels between symbiosis and my professional relationships in academia. The interaction type that occurs between 'professional taxa' can help or hinder the success or survival of one or both 'organisms' involved. Interactions between myself and mentors, administrators, collaborators, and students will be used to illustrate use of symbiotic theory to navigate the symbiotic web of the university system. I will discuss how to maximize mutualisms, stop wasting time on (some) commensalisms, and avoid or negate parasitism. Adaptive approaches include cost-benefit analyses and increased up-regulation of recognition mechanisms. I will also discuss how an NSF ADVANCE program, PACE, helped transform opportunities (and change symbiotic outcomes) for women in science at my university.

The 7 habits of a highly successful family friendly mentor

Genet M. Tulgetske
University of California, U.S.A.

Several recent studies agree that effective mentorship is crucial to the success of women in science. For many women, the ability to be "family friendly" is a major contributor to effective mentoring. In fact, NSF recently recognized the need for more family friendly policies to increase participation and retention of women in science. In this talk, I will describe seven habits of a family friendly mentor from the perspective of a recent PhD, outlining the characteristics women and non traditional graduate students and postdocs seek most in an effective mentor. I hope, through this talk, to inspire young/early career entomologists to actively seek mentoring that will enhance their academic and professional experiences and to encourage established researchers to provide family friendly mentoring to women and non traditional students and postdocs attempting to juggle families and achieve successful careers in entomology.

The Red palm weevil, *Rhynchophorus ferrugineus* (Olivier) (Coleoptera: Curculionidae), an entomological 'elephant in the room'

Paul Rugman-Jones[1], Christina Hoddle[2], Mark Hoddle[3], Richard Stouthamer[4]

[1]*University of California Riverside, U.S.A.,* [2]*University of California Riverside, U.S.A.,* [3]*University of California Riverside, U.S.A.,* [4]*University of California Riverside, U.S.A.*

Elephant-like in size and form, the red palm weevil (RPW), Rhynchophorus ferrugineus, is widely considered the most damaging insect pest of palms in the world. Originally native to southern Asia and Melanesia, RPW has invaded much of the Middle East and Mediterranean basin in recent decades, and now poses a serious threat to commercial and landscape plantings of palms in North America. Despite its large size (20-40 mm), confusion remains over the specific status of this pest. Coloration of adult RPW is extremely variable, ranging from predominantly reddish-brown to almost black but with a distinct red stripe. This has historically led to the classification of color-defined variants as distinct species. However, based on morphological, molecular-genetic and breeding data, RPW is currently considered a single species. Using sequences of mitochondrial and nuclear DNA, we re-examined genetic variation among RPW specimens collected throughout its native and invaded range and found compelling evidence that RPW is in fact a complex of two species: one widespread and highly invasive; and, one with a relatively limited known distribution. The latter species recently showed up in California and may have gone undetected in other areas. Accurate identification is likely to be critical to the successful development and implementation of control strategies for these two species, and this 'elephant in the room' can no longer go unaddressed.

Click beetles (Coleoptera: Elateridae) of Maharashtra: A case study for Indian Elateridae

Amol Prabhakar Patwardhan[1], Raghunandan Prabhakar Athalye[2]
[1]K. J. Somaiya College of Science & Commerce, India, [2]B.N. Bandodkar College of Science, India

Maharashtra is the third largest state of India. On the western side lies north Western Ghats and Konkan. Central part of the state is semi arid while eastern part has dry deciduous forest. Out of the 475 species of Elaterida of India, as recorded in literature, 52 species under 26 genera were reported from different parts of Maharashtra. Specimens were collected from different regions of the state. The specimens were brought to the laboratory and kept alive in the terrarium as far as possible. They were fed with different types of food. A preliminary study of the jump with respect to the morphometry was carried out. The dead specimens were preserved in 70% alcohol. They were studied for their taxonomy.

Mitochondrial DNA phylogeoraphy of Japanese population of *Phelotrupes auratus* (Coleoptera, Geotrupidae) and implications for conservation

Mayumi Akamine[1], Kiyoto Maekawa[2], Masahiro Kon[3]

[1]Hirosaki University, Japan, [2]University of Toyama, Japan, [3]Kyoto, Japan

In biological conservation, taxonomic classification considering evolutionary significant units is important. Phelotrupes auratus (Motschulsky), a coprophagous beetle distributed throughout most of the Japanese archipelago, is listed in the Red Data Book of Japan as being near threatened in several prefectures of the country. Given the current conservation status of this species, knowing the precise taxonomic and phylogeographic characteristics of P. auratus populations is important for the conservation of this species. Partial sequence data of the mitochondrial cytochrome c oxidase subunit I gene (745 bp) of 57 P. auratus specimens from around Japan were compared with a subspecies classification based on mainly geographic color variation. A total of 42 haplotypes were identified and phylogenetic trees inferred using maximum parsimony, neighbor joining, and Bayesian inference methods were highly congruent. The reconstructed phylogenies suggested that the P. auratus populations could be separated into two distinct lineages: Group A consisted of 35 haplotypes from the islands of Honshu, Shikoku, and Hokkaido, and Group B consisted of seven haplotypes from the islands of Kyushu and Yakushima. Group A could further be subdivided into sublineages A-1 and A-2, which consisted of 11 haplotypes from eastern Honshu and Hokkaido and 10 haplotypes from western Honshu and Shikoku, respectively. The average genetic distances within Group A were positively correlated to the geographic distance between sampling localities. While the phylogenetic relationships among haplotypes did not correspond with the subspecies classification based mainly on geographic color variation, the findings suggest that these two lineages need to be conserved separately.

Comparative embryology of adephagan beetles: Its phylogenetic implications

Yukimasa Kobayashi
Tokyo Metropolitan University, Japan

The embryological features of three adephagans, Dineutus mellyi (Gyrinidae), Carabus insulicola (Carabidae), and Hydaticus pacificus (Dytiscidae), were discussed with emphasis their phylogenetic implications. In Dineutus, ten pairs of tracheal gills arise in the abdominal pleura which originate in subcoxae; thus, our observation denies the interpretation that the tracheal gills are homologous with thoracic legs. In Carabus, despite the absence of larval abdominal legs, two pairs of appendage-like swellings, the medial and lateral ones, are tentatively formed on both sides of each of the first eight abdominal segments. The medial swellings in the first abdominal segment develop into pleuropodia. Those in other segments are serially homologous with pleuropodia, but they become flattened and form the larval hypopleura. The lateral swellings, which soon disappear, arise in the subcoxal parts of the medial swellings. The subcoxal parts become the larval abdominal epipleura; thus, lateral swellings can be regarded as temporal subcoxal projections. Considering the subcoxal origin of the tracheal gills in the aquatic Dineutus, the lateral swellings of the terrestrial Carabus might be the vestiges of tracheal gills. In Hydaticus, no appendage-like projections other than pleuropodia appear in the abdominal segments. In both Dineutus and Carabus, the last (10th) larval abdominal segment is formed by fusion of the embryonic 10th and 11th segments, whereas in Hydaticus, the last (9th) segment is formed by fusion of the embryonic 9th and 10th segments (11th segment is highly reduced). These findings suggest the higher position of the Dytiscidae in Adephaga and the aquatic origin of Adephaga.

First morphology-based phylogeny of the Saprininae subfamily (Coleoptera:Histeridae) shows remarkable shifts in their biologies.

Tomas Lackner[1], Kazunori Yoshizawa[2]

[1]Czech University of Life Sciences, Czech Republic, [2]Hokkaido University, Japan

Phylogenetic analyses were performed based on the type species of each sub(genus) of the Saprininae occurring around the world, with exclusion of three taxa that were not available. 11 taxa were also included to test the monophyly of the Saprininae. The total number of in-group taxa was 72. In total, 95 morphological characters of adults were scored and analysed to determine the relationships between the (sub)genera of the Saprininae . Cladograms were rooted with exemplars of Dendrophilinae, Bacaniini, Abraeinae and Anapleini. Results confirm the monophyly of the subfamily supported by an autapomorphy (presence of sensory structures of antenna, unique among the Histeridae), as well as other weaker autapomorphies. Basal-most taxa of the subfamily are mostly inquilinous or myrmecophilous, however, inquiliny itself is estimated to have evolved at least five times and myrmecophily three times independently within the Saprininae . Termitoxeny has evolved two times independently within the Saprininae . Most derived taxa of the Saprininae are psammophilous, and psammophily is thought to have evolved once and has been subsequently lost several times. Ecological adaptation for life in caves (troglophily) has likewise evolved two times independently. Because of the low resolution of the cladogram, no major changes in the Saprininae classification are proposed and three informal groups of taxa are instead designated as pointers for the future studies. Additional evidence is needed for a reliable placement of the aforementioned 'groups' as well as for the clarifying the inter-relationships of the heterogeneous and ill-defined genera.

Genetic differentiation and phylogeography of *Neolucanus* (Coleoptera: Lucanidae) in Taiwan

Cheng-Lung Tsai[1], Wen-Bin Yeh[2]

[1]National Chung Hsing University, Taichung, Taiwan, Taiwan, [2]National Chung Hsing University, Taiwan

Neolucanus stag beetles distributed in Oriental and Paleoarctic regions, and five known species involving four subspecies were recorded in Taiwan. Taxonomic debates among N. swinhoei Bates, N. eugeniae Bomans, N. doro doro Mizunuma, and N. doro horaguchii Nagai had lasted for a long time. It is generally believed that these diurnal species with overlapping morphological characters differentiated in different mountain areas was owing to weak flight capability and short adult stage. To clarify taxonomic status of these stag beetles, we compared shape of canthus, number of serrate mandible teeth, elytra coloration, elytra luster, and molecular characteristics, i.e, COI, 16S rDNA, 28S rDNA, and wingless, between populations. Morphometric analysis showed two groups of N. swinhoei and the others. However, phylogenetic tree combined COI and 16S rDNA using Bayesian and MP inferences showed four major lineages; and no or low variation was found in 28S rDNA and wingless. Intermingling DNA sequences from different populations in each lineage indicated the possibility of hybridization or introgression event between these species. Results in this study did not completely consistent with the previous taxonomic studies. Weak flight capability and short adult stage reducing gene flow possibility between populations may accumulate variations in local areas. Furthermore, we believed multiple refugia and/or invasions have been occurred in these stag beetles during Pleistocene, which would affect their current distribution and lead to ambiguous in taxonomic recognition.

Phylogenetic position of termitophilous rove beetle tribe Termitohospitini (Coleoptera: Staphylinidae).

Taisuke Kanao[1], Taro K Eldredge[2], Munetoshi Maruyama[3]

[1]Kyushu University, Japan, [2]University of Kansas, U.S.A., [3]The Kyushu University Museum, Japan

Rove beetles (Coleoptera: Staphylinidae) are the most ecologically and morphologically diverse insect guests of termite colonies (so-called "termitophiles"). More than 650 species are known from the subfamily Aleocharinae; indeed, there are 12 aleocharine tribes composed exclusively of termitophilous species. One such tribe is Termitohospitini. The species in this tribe exhibit high morphological diversity, with the body form varying from limuloid to physogastric. Two species, Sinophilus yukoae and Japanophilus hojoi are known to have a distinctive sensory patch on segment III of the maxillary palpus. Although this structure had not been found in other species of Aleocharinae, we have now discovered it in other Termitohospitini species, as well as in the genus Myllaena (tribe Myllaenini). We therefore investigated the phylogenetic relationship between Termitohospitini and Myllaenini. This analysis revealed that the Myllaenini formed a monophyletic group with Termitohospitini and Masuriini. The sister group of this clade is estimated to be Pronomaeini, which previously had been considered close to Myllaenini. This topology is supported strongly by mouthpart characters, and we therefore synonymize Termitohospitini and Masuriini with Myllaenini. Based on host termite records, we hypothesize that Termitohospitini may have originated in the Neotropical region, and spread to the Oriental region where the tribe evolved its autapomorphic characters. Our results indicate that the present organization of termitophilous aleocharine systematics may tend to overemphasize the unique characters of each group.

Phylogeny and biology of *Ischyrosonychini* Chapuis 1875 (Coleoptera, Chrysomelidae, Cassidinae)

Choru Shin
University of Kansas, U.S.A.

Leaf beetles (Coleoptera: Chrysomelidae) form one of the largest beetle families, with most members feeding on living plants. Members of the subfamily Cassidinae often show very colorful patterns, diverse morphology, and many interesting behaviors. The New World tribe Ischyrosonychini Chapuis includes seven genera and 66 species. It is divided into three distinct groups (former tribes Asterizini+Ischyrosonychini+Physonotini). However, synapomorphies uniting these three groups were previously unknown. I conducted a phylogenetic analysis on Cassidinae s. str. to address this problem. A stridulatory file on the vertex in both male and female adults was discovered to represent a synapomorphy for the tribe; stridulation using these files was recorded. The genera Asteriza Chevrolat, Eurypedus Gistel, and Cistudinella Champion are shown to be reciprocally monophyletic and the "physonotine" genera (Enagria Spaeth, Eurypepla Boheman, Physonota Boheman, Platycycla Boheman) are shown to represent a paraphyletic group. Detailed morphological and biological studies were conducted. Adult color change in Eurypepla calochroma (Blake) was observed and a detailed study of the structure of the pronotum and elytra was conducted by histological sectioning. Larval urogomphi are discussed and a distribution map is provided.

Revision of the *Dorcus velutinus* species group (Coleoptera: Lucanidae) through integrative taxonomic approach

Sang Il Kim[1], Taeman Han[2], Tae Hwa Kang[3], Jongchel Jeong[4], Youngbo Lee[5], Naomi E. Pierce[6], Philip D. Perkins[7], Hae-Chul Park Park[8]

[1]Harvard University, U.S.A., [2]National Academy of Agricultural Science, Republic of Korea, [3]National Academy of Agricultural Science, Suwon, Republic of Korea, [4]Seodaemun Museum of Natural History, Republic of Korea, [5]National Academy of Agricultural Science, Republic of Korea, [6]Harvard University, U.S.A., [7]Harvard University, U.S.A., [8]National Academy of Agricultural Science, Republic of Korea

The Dorcus velutinus species group consists of six species and one subspecies described to date: Dorcus velutinus Thomson, D. ursulus Arrow, D. taiwanicus Nakane et Makino, D. tenuihirsutus Kim, D. japonicus Nakane et Makino, D. carinulatus carinulatus Nagel, and D. carinulatus koreanus (Jang et Kawai). To examine the species entity and their phylogenetic relationships, both molecular analysis using 16S rRNA partial sequences of mtDNA and morphological examination were performed. For the morphological study, the following type specimens were examined: Gnaphaloryx cinereus, D. ursulus, D. taiwanicus and D. japonicus. As a result, we not only recognized distinct genetic divergences among all existing species but also infer that D. velutinus may be composed of three pseudocryptic species from five geographical regions: (i) The true D. velutinus from India; (ii) D. sp. nov. 1 from Thailand, Vietnam and China; and (iii) D. sp. nov. 2 from Cambodia. While the morphology showed only subtle differences, the genetic divergences were remarkable, ranging from 6.8% to 8.2%. The Indian specimens were regarded as the true D. velutinus in the present study, but this needs to be confirmed by examining the currently unavailable type specimen. In addition, we propose that the two species, D. mineti and D. cylindricus, to be additionally incorporated into this species group based on molecular and morphological evidences. Lastly, nomenclatural problem of synonymizing a species without examining the type specimen was recognized in D. bobi under D. cylindricus, but further study is needed.

The oldest fossil Cleroidea and Cucujoidea

Jiri Kolibac
Moravian Museum, Czech Republic

The Early Cretaceous and Middle Jurassic deposits of northern China have recently yielded rich fossil records of beetles. In particular, finds from the volcanic deposits of the Jiulongshan formation (c. 165 Ma) are among the oldest known beetle fossils of the suborder Polyphaga. Some of them are extraordinarily well-preserved and provide interesting insight into the evolution of morphological characters. In cooperation with Prof. Huang D.-Y. of the Nanjing Institute of Geology and Palaeontology, China, a rich body of material is studied, consisting of the Mesozoic family Parandrexidae and several extinct and extant cucujoid and cleroid families. The fossils exhibit a large number of interesting details including, for example, the mouth parts, cranial morphology, thoracic segments, and male and female genitalia. Implications for character evolution and phylogeny in Cucujiformia may therefore be considered.

The complete mitochondrial genome of the Mediterranean cryptic species of the whitefly *Bemisia tabaci* (Gennadius) (Hemiptera: Aleyrodidae) complex

Hua-Ling Wang
Zhejiang University, China

The whitefly Bemisia tabaci is a species complex containing at least 28 morphologically indistinguishable cryptic species. Among these cryptic species, only the mitochondrial genome of the New World has been fully sequenced. The Mediterranean (MED) cryptic species of the B. tabaci complex is an important agricultural pest causing significant yield loss to crop production. In this study, we sequenced the complete mitochondrial genome of MED. The genome is a circular molecule of 15,890 bp, encodes 37 genes including 13 protein coding genes (PCGs), two ribosomal RNAs (srRNA and lrRNA) and 22 transfer RNAs. In addition, it contains two non-coding A+T-rich regions which are rarely found in other metazoan mitochondrial genomes except the New World cryptic species of the B. tabaci complex. All the stop codons of protein coding genes are TAA or TAG, except for coxII that terminate with an incomplete stop codon. 22 tRNAs were found and most of the tRNAs could be folded as classic clover-leaf structures, except the tRNA-SerUCU, which lose the DHU arm. Comparison of the evolution rate of the mitochondrial genes between MED and New World showed that COII has the lowest evolutionary rates while nd4/nd4L the highest. The complete mitochondrial genome of MED will provide new information to resolving the phylogenetic relationship of the B. tabaci species complex as well as identifying ideal genetic markers for cryptic species identification.

Phylogenetic analysis of the plant bug subtribes Monaloniina and Odoniellina (Heteroptera: Miridae: Bryocorinae)

Anna Alekseevna Namyatova[1], Gerasimos Cassis[2]

[1]*University of New South Wales, Australia,* [2]*University of New South Wales, Australia*

The plant bug subtribes Monaloniina and Odoniellina (Hemiptera: Miridae: Dicyphini) have been considered as closely related plant bug taxa, comprising 41 genera (Schuh & Slater, 1995). They are found mostly in the Afrotropical, Oriental and Australian regions, as well as islands of the southwest Pacific. Some species are important pests of foodplants, such as cocoa, cotton and cashews. Representatives of these subtribes are morphologically diverse, varying dramatically in size, coloration, vestiture, and presence or absence of exaggerated cuticular outgrowths. No comprehensive study has been undertaken of these character systems and the classification is untested. We report on a novel reclassification of these taxa, based on the first comprehensive examination of included taxa, resulting in the exclusion of four genera from these suprageneric groups. We present the results of two phylogenetic analyses, based on morphological characters of the Monaloniina and Odoniellina. The first analysis for the tribe Dicyphini s.l. demonstrates that these subtribes together form a monophyletic group with high support. The genus Felisacus, which was previously included to the subtribe Monaloniina, is excluded from this subtribe, and its relationship was found to be more distant to the redefined monaloniines. The second phylogenetic analysis of 79 terminal taxa, showed that the Monaloniina s.l. and Odoniellina s.l. are polyphyletic.

The fossil reduviids (Heteroptera) of Messel (Germany) and Green River (USA)

Marianne Koch[1], Sonja Wedmann[2]

[1]Senckenberg Forschungsinstitut und Naturmuseum Frankfurt am Main, Germany, [2]Senckenberg Forschungsinstitut und Naturmuseum Frankfurt am Main, Germany

Two worldwide well-known fossil sites are the UNESCO World Heritage Site Grube Messel located in Germany and the Green River Formation in the United States of America. Both sites are of similar age with ~ 47 Ma (Messel) and ~ 50 Ma (Green River). The Heteroptera are a very interesting insect group, which until now has been only poorly studied in both sites. More than 1,700 specimens of Heteroptera from Messel and 1,100 specimens of Green River are stored in the collections of Senckenberg Forschungsinstitut und Naturmuseum, Frankfurt am Main (Germany) and the National Museum of Natural History Smithsonian Institution, Washington D.C. (USA). With more than 6,600 extant species, the Reduviidae are the second largest group within the Heteroptera. Investigations on the systematic relationships among the assassin bugs are still in progress; e. g., different authors classified the Reduviidae from 21 up to 32 subfamilies. Until now, more than 60 fossil specimens of assassin bugs from Messel were found and the extant groups Harpactorinae and Elasmodeminae can be identified. Among the Harpactorinae, some fossils can be determined as Harpactorini, Ectinoderini and Apiomerini. Since extant Ectinoderini are restricted to the area between Sri Lanka and New Guinea, the new fossils enlarge the known geographical range of this group considerably. About 25 reduviid specimens were detected in the Green River collection; in regard to reduviids, this site seems to have a lower biodiversity than Messel.

Fossil lace bugs (Heteroptera: Tingidae) from the Eocene

Sonja Wedmann[1], Marianne Koch[2]
[1]*Senckenberg Research Institute, Germany,* [2]*Senckenberg Research Institute, Germany*

A characteristic feature of lace bugs (Tingidae) is the distinctive lacelike network of raised ridges, which is present on the hemelytra and on the pronotum of two of the three subgroups. These subgroups comprise the Cantacaderinae and the Tinginae, while the Vianaidinae have a rather smooth body surface. Both adults and nymphs of the Tingidae are phytophagous. The 260 tingid genera with more than 2100 extant species are widely distributed in the different regions of the world. Their size ranges from about 2 mm to more than 8 mm. The fossil record of lace bugs comprises about 40 species, with oldest representatives in the Cretaceous. Most of the fossil taxa are described from amber, and here mostly from Eocene Baltic amber. Nevertheless, very well preserved specimens are also found in sedimentary rocks. Several fossil genera and species of lace bugs from the Eocene Fossillagerstatte Grube Messel (Germany) have been described, and now a new analysis of old and new findings is given. An ongoing study of heteropterans from the Eocene Fossillagerstatte Green River (USA) illuminates the poor biodiversity of tingids preserved in this site.

Taxonomic revision of the family Cixiidae from Korea (Homoptera: Fulgoromorpha)

Mohammad Atikur Rahman[1], Yong Jung Kwon[2]

[1]School of Applied Biosciences, Coll. of Agr. & Life Sci., Kyungpook National University, Republic of Korea, [2]School of Applied Biosciences, Coll. of Agr. & Life Sci., Kyungpook National University, Republic of Korea

This paper completes a taxonomic revision of the planthopper family Cixiidae from Korea. Eight genera are recognized in the Korean fauna: Andes Stal, 1866, Atretus Emeljanov, 2006, Reptalus Emeljanov, 1971, Pentastiridius Kirschbaum, 1868, Oecleopsis Emeljanov, 1971, Cixius Latreille, 1804, Macrocixius Matsumura, 1914, Kuvera Distant, 1906. Among them, two genera, Atretus and Macrocixius, are recorded for the first time in Korea. Thirty six species, fourteen of which are new to science and eleven are new to Korea, are recognized in the Korean fauna: Atretus trifurcus sp. nov., Pentastiridius unjangsanensis sp. nov., P. seoguensis sp. nov., P. jillyangensis sp. nov., Cixius jejudoensis sp. nov., C. mayisanensis sp. nov., C. obongsanensis sp. nov., C. pohyonsanensis sp. nov., C. sigmoidensis sp. nov., C. wanjonensis sp. nov., C. weonhyosanensis sp. nov., Kuvera hallasanensis sp. nov., K. hagilsanensis sp. nov., K. yecheonensis sp. nov., Reptalus iguchii (Matsumura, 1914), P. hachijonis (Matsumura, 1914), P. harimaensis (Matsumura, 1914), C. flavescens Matsumura, 1914, C. hakonensis Matsumura, 1914, C. heydenii Kirschbaum, 1868, C. ibukisanus Matsumura, 1914, C. nawae Matsumura, 1914, C. towadensis Matsumura, 1914, C. okinawanus Matsumura, 1936 and Macrocixius giganteus Matsumura, 1914. New combinations proposed are: Reptalus iguchii (Matsumura, 1914) comb. nov., Pentastiridius hachijonis (Matsumura, 1914) comb. nov. and P. harimaensis (Matsumura, 1914) comb. nov. Previously recorded three species from Korea are not available in current investigation: Cixius nervosus (Linnaeus, 1758); Kuvera ligustri Matsumura, 1914 and Pentastiridius angusticeps (Horvath, 1892). Identification keys to tribe, genera and species are provided.

Systematic review of the sub-family Phylinae (Heteroptera: Miridae) in the Korean Peninsula with discussion on phylogenetic relationship within family Miridae

Ram Keshari Duwal[1], Sunghoon Jung[2], Seunghwan Lee[3]

[1]Seoul National University, Republic of Korea, [2]University of California, U.S.A., [3]Seoul National University, Republic of Korea

The Korean Peninsula is located in temperate ecozones which shelter Palearctic flora and fauna. Because of small size and easily fragileness the tiny phyline bugs has been poorly studied from this region. Herein, this study tries to accomplish revision of subfamily Phylinae (Miridae) in the Korean Peninsula which document a total of 85 species in 26 genera. Due to the survey from 2008 to 2011 many species are described and reported which were fragmentally reported (Duwal and Lee, 2011, Duwal, et al., 2010; 2012 (to be published)) and many species await description. Many species like Campylomma chinense Schuh, 1984; C. miyamotoi Yasunaga, 2001; Europiella artemisiae (Becker, 1864); E. kiritshenkoi Kulik, 1975; E. miyamotoi (Kerzhner, 1988), Pherolepis kiritshenkoi (Kerzhner, 1970) are reported for the first time in Korea. Tytthus koreanus Josifov and Kerzhner, 1972 and Hallodapus fenestratus Linnavuori, 1961 are synonymized to Tytthus chinensis (Stal, 1859) and Hallodapus centrimaculatus (Poppius, 1914) respectively, and Europiella lividella (Kerzhner, 1973) and Parapsallus vitellinus (Scholtz, 1847) are re-combined to their original status. The feeding habits of phyline bugs are not clear though most of them are considered as phytophagous, but tribes like Hallodapini, Pilophorini and some groups of phylines are also considered as predatory/ or omnivorous. Finally, phylogenetic analysis of Family Miridae will be discussed including morphometric and molecular data to see the relationship and placements of groups within Subfamily and tribes.

Faunistic studies of tribe Halyini (Hemiptera, Pentatomidae, Pentatominae) of Pakstan with description of nine new species

Abdul Manan Shaikh[1], Nasreen Memon[2], Manssor Ali Shah[3], Nadir Ali Birmani[4]

[1]Shah Abdul Latif University, Khairpur, Pakistan, [2]University of Sindh, Jamshoro, Pakistan, [3]University of Sindh, Jamshoro, Pakistan, [4]Shah Abdul Latif University, Pakistan

According to available literature a large number of species have been added to the tribe Halyini from time to time and also place of different species changed from one genus to other by different workers, new records are also explored time to time, because of this, their distributional range further increased. There are about 31 genera and more than 110 species from Pakistan and different areas of adjoining countries are described by different authors. During present study collection of Berry Bugs species were carried out from different areas of Pakistan. A total of 5600 specimens were collected and preserved as per standard procedure. The material was studied, compared and classified according to available literature. During present studies, twenty six species are studied including nine new species of four genera are described. In addition seventeen already described species of seven genera have also been collected and studied from different localities and different host plants in Pakistan.

Revision of Asian species of genus *Halys* Fabricius (Hemiptera: Pentatomidae: Halyini) in addition to description of new species from Pakistan

Nasreen Kousar Memon
University of Sindh, Pakistan

Halys is a cosmopolitan oriental genus of tribe halyini, found in almost all parts of the world. In Pakistan they are found on a number of food plants and plants of commercial importance such as Shesham, Babur and Mulberry trees. Present study includes eight species from oriental region of Asia; H. fabricii Fabricius, H. nilgiriensis Distan, H. shaista Ghauri, H. serrigera Westwood and H. sulcatus, including three new species H. hyderabadiensis n. sp, H. mulbariensis n.sp, H. noakotensis n.sp, one from Punjab province and two from Sindh provinces, Pakistan respectively. The new species are described on the basis of external morphological characters and the description of internal and external male and female genitalia with special references to scent gland apparatus. The new species are compared with their closely allied species, and key of eight species including new species is given here. The localities of new species are addition in the geographical distribution of genus halys in the existing literature.

Three new species of the genus *Polypedilum* Kieffer (Diptera: Chironomidae) from the Yaeyama Islands, Japan, with comments on the taxonomic implication of the superior volsella

Nao Yamamoto[1], Masaru Yamamoto[2], Toshiya Hirowatari[3]
[1]Osaka Prefecture University, Japan, [2]Shimonoseki, Yamaguchi, Japan, [3]Osaka Prefecture University, Japan

Polypedilum Kieffer, 1912 is one of the largest genera in the family Chironomidae and at least 115 species have been described in Japan. According to Sæther et al. (2010), this genus has been divided into eight subgenera and the structure of the superior volsella is treated as one of the most important taxonomic characters for separating the subgenera and inferring the phylogenetic relationship among them. In the present study, three new species from the Yaeyama Islands, the Ryukyus, Japan, are described and figured based on male adults. Two of the new species, Polypedilum sp. 1, and P. sp. 2, are assigned to the subgenus Polypedilum. One species, Polypedilum sp. 3, is not assigned to any subgenus due to the unique structure of the superior volsella, and it may be justified to erect a new subgenus for it in future study. We would in any case hesitate to erect a new subgenus based solely on it, because we are rather sceptical whether the structure or shape of the superior volsella should be treated as one of the most important taxonomic characters for separating the subgenera. This species contains elements of both Uresipedilum and a part of Tripodura on the shape of superior volsella. Furthermore, as the shapes of the superior volsellae are highly variable, it appears that a tendency of continual variation is present throughout each subgenus. These might destabilize some positions of the subgenera defined by the features of the superior volsella in the genus Polypedilum.

Bluetongue (BT) is an infectious, non-contagious disease of ruminants which inflicts major losses on subsistence sheep farmers in southern India. The agent that causes this disease (bluetongue virus: BTV) is transmitted by Culicoides biting midges (Diptera: Ceratopogonidae). The India Bluetongue Vector Network (IBVNet) is a three year Indo-UK collaborative project aiming to examine ways to both predict and reduce the impact of BTV by monitoring monsoon-related Culicoides activity and exploring affordable methods for their control. Key to developing multi-state surveys of Culicoides populations, and vector competence and control studies is a sound taxonomic understanding of the livestock-associated Culicoides present. To achieve this livestock-associated adult Culicoides were collected using ultraviolet (UV) light-suction traps from three states in southern India severely affected by BTV outbreaks (Andra Pradesh, Karnataka and Tamil Nadu). Using a combination of non-destructive DNA extraction, DNA barcoding and preservation of slide-mounted voucher specimens, high quality digital images of key morphological characteristics were made and assessed in relation to the results of phylogenetic analysis of the corresponding DNA Barcode sequences produced for the mitochondrially encoded cytochrome c oxidase I (MT-CO1) region. The results of this analysis are being used to generate a taxonomic guide to the Culicoides of southern India relevant to BTV epidemiology and place the Indian Culicoides fauna in a global perspective.

A systematic study of the genus Chrysotoxum Meigen (Diptera, Syrphidae) in Korea

Sang Wook Suk[1], Ho Yeon Han[2]

[1]Yonsei University, Republic of Korea, [2]Yonsei University, Republic of Korea

The family Syrphidae is distributed worldwide, with the greatest species diversity in the New World Tropics. More than 6,000 species have been described so far. The genus Chrysotoxum Meigen includes fairly large flies with body coloration similar to wasps. There are over 100 known Chrysotoxum species of which 74 species occur in the Palaearctic region. They can be easily distinguished from other genera by the follow characteristics: 1) humeri bare; 2) antenna usually longer than head and positioned horizontally in lateral view; 3) wing vein R4+5 dipped posteriorly; and 4) abdomen black with yellow bars or bands or characteristic black arcuate markings. As a result of systematic study of Korean Chrysotoxum, we have recognized 10 valid species, including two species new to science, two newly recorded species in Korea (C. tuberculatum, C. ramphostomus), and six previously known Korean species (C. biguttatum, C. coreanum, C. grande, C. sapporense, C. sibiricum, C. vernale). In addition, we synonymized C. shirakii with C. sapporense. We here provide a key and photographs with their key characters indicated.

Ulidiidae (Diptera) systematic - Molecular and morphological aspects

Tatiana Galinskaya
Lomonosov Moscow State University, Russia

Ulidiidae is a small Tephritoidea family. Ulidiidae are often combined with Otitidae in one family, named Ulidiidae or Otitidae. Our analysis of the genital structures revealed that Ulidiidae + Otitidae form a paraphyletic group, referring to derived Tephritoidea. Therefore, we consider Ulidiidae and Otitidae as separate families. We studied sequences of the COI gene of 58 specimens of 25 species of Ulidiidae and Otitidae. COI was shown to be an effective marker to distinguish Ulidiidae and Otitidae species, except for the genus Melieria (Otitidae). Melieria shows the highest level of intraspecies differences and smallest - of interspecific with high support at all cladograms. This suggests that Melieria is a young genus, being is at the stage of intense speciation. Monophyly of the family Ulidiidae with the inclusion of Homalocephala not confirmed on any of the molecular reconstruction. The position of the genus Homalocephala is indefinite. On the MP and NJ cladograms it forms a sister group to the Otitidae. On the ML and Bayes cladograms Homalocephala species are included in clusters of both families as their basal elements. Our study of genital structures has shown that the genus Homalocephala cannot be included neither in Ulidiidae, nor in Otitidae. It represents the separate clade within the Tephritoidea, which requires further study. In all cladograms genera Timia and Ulidia form mixed cluster. This is consistent with the morphological data on which these genera are very close to each other under the external morphology and genital structures and have little or no hiatus.

Systematic study of the family Bombyliidae (Diptera: Asiloidea) in Korea

Yong-Bong Lee[1], Ho-Yeon Han[2]

[1]Yonsei University, Republic of Korea, [2]Yonsei University, Republic of Korea

Bee flies (Diptera: Bombyliidae) are distributed worldwide with more than 4,500 known species. This family occurs in broad variety of habitats and ecosystems, but its highest species diversity concentrated in arid and semi-arid regions. Adult bombyliids mostly feed on nectar of flowers, and immatures are poorly known. According to the previous records, they are primarily parasitods of other insects. In the process of revising Korean Bombyliidae, we have recognized 31 species of 10 genera, among which five species are new to Korea. Unfortunately, we still have not confirmed 7 previously recorded Korean species. Among them, we believe that we have not collected Bombylius lejostomus (TL: North Korea) and Ligyra flavofasciata (TL: China) yet, and other five species could possibly be based on erroneous previous identifications. In addition, we recognized nine species identified only to generic level. They are possibly either new species or uncertain species needed more investigation for accurate identification. We here provide an updated list of Korean Bombyliidae, a key, and photographs with their key characters indicated.

Utility of COI, COII and ND4 genes for discriminating forensically important Diptera

Alicia Eva Timm[1], Trevor Stamper[2], Gregory Dahlem[3], Ronald Debry[4]

[1]Rhodes University, South Africa, [2]Findlay University, U.S.A., [3]Northern Kentucky University, U.S.A., [4]University of Cincinnati, U.S.A.

One of the most debated topics in molecular taxonomy concerns the region of DNA that is used to identify species. For forensic entomology, where species are well characterised, it is worth exploring whether or not some DNA region that is different from the standardized barcode region can provide better species discrimination. Our objective was to investigate the use of COI and COII, the two most commonly used genes for identifying species of this group, as well as the ND4 gene, which shows promise for robust species identification. Since the use of molecular identification is most challenging among closely related species sister species, pairs of different genera of the Calliphoridae and Sarcophagidae were included in analyses. The data set was analysed using the three concatenated genes, each individual gene, and sliding windows consisting of 600bp. Of the three genes analysed, COI yielded the highest level of total intraspecific nucleotide diversity, followed by COII and ND4. Within the COI gene, the optimal location for species discrimination was situated towards the 3' end of the gene. The effect of fragment length on nucleotide divergence and phylogeny was investigated by examining fragments with 200bp increments. Results showed that fragment lengths of at least 1000bp are necessary to ensure that close to 100% total diversity is sampled. Therefore, we recommend that the optimal fragment for identifying forensically important Diptera is located towards the 3' end of the COI gene and consists of 1000bp to ensure greater diversity coverage.

A systematic revision of the Korean Lauxaniidae (Insecta: Diptera)

Hyun-Suk Lee[1], Ho-Yeon Han[2]

[1]Yonsei University, Wonju, Republic of Korea, [2]Yonsei University, Wonju, Republic of Korea

The Lauxaniidae is one of the large families of acalyptrate flies (about 1,550 world species under 142 genera). They are known to occur in all the zoogeographical regions. Adult flies are found in a wide range of habitats. They are common in moist shady undergrowth, grassland, all forest types. Their larvae are saprophagous and are found in leaf litter, decaying vegetation and similar habitats. The family can be distinguished from the other acalyptrate flies by the combination of the following characteristics: 1) postocellar seta inclinate to cruciate, 2) true vibrissae absent, 3) dorsal preapical seta present on tibiae and 4) costal vein not broken. In Korea, the number of previously recorded species is 33, among which 10 species have been given Korean names. As a result of our systematic investigation of the Korean Lauxaniidae, we have recognized 95 species, including 34 newly recorded Korean species, 21 possible new species and 7 species with uncertain identity. We conducted a cladistic analysis to infer generic relationships among the genera in Palaearctic region. We also inferred specific relationships of six selected genera in Korea. We also made DNA barcoding analysis, which turned out to be highly effective in resolving some taxonomic problem caused by sibling species complex.

Heterogeneity and prevalence of cryptic species in *Wolbachia* infected uzifly *Exorista sorbillans* (Diptera:Tachinidae)

Puttaraju Hosagavi Puttegowda[1], Guruprasad N.M.[2]

[1]*Bangalore University, India,* [2]*Bangalore University, India*

Inherited bacterial symbionts from the genus Wolbachia have attracted much attention by virtue of their ability to manipulate the reproduction of their arthropod hosts. Speciation in insects induced or facilitated by symbionts Wolbachia which can manipulate host reproduction and induce reproductive isolation. The potential importance of these bacteria has been underlined by surveys, which have estimated that 20% of insect species are infected. Cytoplasmic Incompatibility (CI) is the one of the important reproductive manipulation induced by the Wolbachia. Previous studies have clearly established high prevalence of Wolbachia infection in the Uzifly Exorista sorbillans a tachinid endoparasite of silkworm. In the present investigation we detected the heterogeneity and cryptic species in E. sorbillans infected with Wolbachia. The DNA finger printing of infected populations was done by using the Randomly Amplified Polymorphic DNA (RAPD). The dendrogram constructed from Un-weighted Pair Group method with Arithmetic Mean (UPGMA) and distance computed using Elucidation distance clearly detected the heterogeneity and prevalence of cryptic species in E. sorbillans populations. This could be the result of geographic isolation and Cytoplasmic Incompatibility (CI) induced by Wolbachia among the Uzifly field populations.

Phylogeny of the mosquito tribe Culicini (Diptera, Culicidae) based on COI sequences and morphology.

Jacques Dubois[1], Ralph E. Harbach[2], Ian J. Kitching[3], C. Lorna Culverwell[4], Yvonne-Marie Linton[5]

[1]Natural History Museum, United Kingdom, [2]Natural History Museum, United Kingdom, [3]Natural History Museum, United Kingdom, [4]Natural History Museum, United Kingdom, [5]Natural History Museum, United Kingdom

The tribe Culicini comprises four genera, including Culex which includes 768 species classified in 26 subgenera. Several of these species are vectors of arboviruses (e.g. West Nile and Japanese encephalitis viruses) and filarial worms that cause disease in humans. Within the framework of an integrated morphological and molecular systematics project, we carried out the first fully integrated study on the phylogenetic relationships within this tribe to investigate and understand the evolution and diversification of this group. Selected species of the tribe Culicini representing all the different genera, subgenera and species groups were sequenced for the COI barcode region and analyzed. We discuss their variability and the phylogenetic signal held separately by the DNA sequences and morphology, and by the combined data, with the aim at elucidating the phylogenetic relationships of supraspecific taxa of this species-rich group.

The phylogeny of chelonine wasps (Hymenoptera: Braconidae) with special reference to the species diversity of the Australian fauna

Rebecca Kittel[1], John T. Jennings[2], Andrew D. Austin[3]

[1]School of Earth and Environmental Sciences, The University of Adelaide, Australia, [2]School of Earth and Environmental Sciences, The University of Adelaide, Australia, [3]School of Earth and Environmental Sciences, The University of Adelaide, Australia

The Cheloninae are a diverse subfamily of braconid wasps which have a global distribution. There are about 1,300 described species in 15 genera, but only 43 species (incl. five introduced species) in four genera are recorded for Australia. Chelonines are egg/larval parasitoids of Lepidoptera and they can be easily distinguished from most other braconids by the presence of a metasomal carapace, where the first three tergites are fused into a dorsal plate. This study aims to assess the phylogenetic relationships among world genera employing sequence data from three genes, cytochrome c oxidase I (CO1), 28S (rDNA) and ef1α (nuclear DNA). Preliminary results show that most genera are monophyletic with the exception of Microchelonus (characterised by the presence of a large pit on the posterior metasoma), which falls within Chelonus. Genera belonging to the tribes Pseudophanerotomini and Phanerotomini, in which all species have sutures on the carapace, form a natural group but neither of the tribes is monophyletic. The species diversity of the Australian fauna, assessed using an integrated approach of COI data and morphology, is huge. The four common genera total more than 70 species, with new taxa found in all major habitat types including the arid zone of central Australia as well as coastal mesic environments.

Phylogeny and higher classification of Mutillidae (Hymenoptera): Re-evaluation based on morphology

Denis John Brothers[1], Arkady S. Lelej[2]

[1]University of KwaZulu-Natal, South Africa, [2]Russian Academy of Sciences, Russia

In 1975 Brothers produced the first phylogenetic analysis and higher classification of Mutillidae (velvet ants) on a world-wide basis, using 43 characters and groundplans for the taxa. Seven subfamilies and several tribes and subtribes were proposed. In 1997 Lelej & Nemkov published an analysis (using 89 characters, many different from those previously used at this level) and proposed ten subfamilies, reflecting several differences in inferred relationships. Slight expansion and reanalysis by Brothers in 1999, taking Lelej & Nemkov's results into account, produced essentially the same results as he had obtained in 1975, however. More than 50 genera, including varied species for each where possible, were individually scored for all morphological characters previously considered in such analyses as well as others used at the genus level, a total of about 190 characters. Four outgroup genera representing those families previously found to be most closely related to Mutillidae were similarly scored. Parsimony analyses were performed, using various options involving additivity of character states and implied weighting of characters. Neither Brothers's nor Lelej's previously proposed phylogenies were fully supported. Several 'taxa' were found probably to be paraphyletic. Different analytic assumptions produced considerable differences in branching patterns. Recognition of a series of higher taxa somewhat intermediate between the earlier schemes proposed by Brothers and Lelej may be justified. However, the inclusion of several characters polymorphic within genera, and the fact that such variation in state expression appears to differ in extent in different parts of the trees found, has undoubtedly confounded the situation.

The phylogeny of Tenthredinidae (Hymenoptera): A morphological perspective

Lars Vilhelmsen
Natural History Museum of Denmark, Denmark

The Tenthredinidae with more than 5.000 described species is the largest family of non-apocritan wasps. The members of this and the other families in the Tenthredinoidea are all herbivorous and are commonly known as sawflies. Tenthredinidae has no obvious autapomorphies and has not been retrieved as monophyletic in any stringent phylogenetic analyses. On the contrary, most other families (Argidae, Cimbicidae, Diprionidae, and Pergidae) in the Tenthredinoidea have repeatedly been placed inside the Tenthredinidae. The current subfamily classification has never been tested cladistically. To evaluate the status of the Tenthredinidae and its subdivisions, a comprehensive morphological data set of 150 characters has been scored for 130 taxa. Character systems are all derived from adult anatomy and include the head, thorax, wings and other body appendages, and the ovipositor apparatus. The data set was analysed with parsimony software under various settings. Preliminary results confirm the monophyly of Tenthredinoidea, the Blasticotomidae being the sister group to all remaining Tenthredinoidea, and the monophyly of Cimbicidae, Diprionidae, and Argidae + Pergidae. The Tenthredinidae is paraphyletic, and none of the subfamilies currently recognized are retrieved as monophyletic under all analytical settings. Topologies are not stable, and many nodes are weakly supported and liable to disappear when the analytical settings are changed. To obtain a robust phylogeny that may serve as the basis for a reclassification and interpretation of the evolutionary history of Tenthredinidae/Tenthredinoidea, it is necessary to tap additional sources of information, first and foremost molecular.

Taxonomic confusion and misidentification of multiple invasive ant species - Multiple current species are species complexes.

Benjamin Hoffmann[1], Alan Andersen[2]

[1]CSIRO, Australia, [2]CSIRO, Australia

Here we detail confusion surrounding the taxonomy and identification of two apparently invasive ant species, Iridomyrmex anceps Roger and Ochetellus glaber Mayr, which are commonly cited in the literature as having been spread widely by human commerce. We provide morphometric data and images strongly suggesting that these two "species" are instead complexes of species that are likely native to many regions where they are purportedly introduced. We take particular interest in the status of species referred to as I. anceps and O. glaber in China, as this is the most northerly distribution of both genera. We then expand our analyses to the recent morphologically based revision of the genus Iridomyrmex (Heterick and Shattuck 2011) as we believe that this revision unjustifiably combines taxa that are very obviously multiple and in several cases very many species, with clear morphological differentiation between populations that are often sympatric and having up to 12% genetic divergence based on CO1 analysis.

Filling the gaps - New lower Cretaceous Hymenoptera and the early evolution of the order

Lars Krogmannn Hoffmann
State Museum of Natural History Stuttgart, Germany

The early evolution of the megadiverse insect order Hymenoptera is of general biological interest as it was accompanied by a dramatic change in biology from phyto- and xylophagy (i.e. sawflies and woodwasps) to parasitoidism (Euhymenoptera, i.e. Orussidae + Apocrita). The phylogeny of Hymenoptera is briefly reviewed based on recently published morphological and molecular data sets, and then used as a framework to examine the biological and phylogenetic implications of two recently discovered fossils from the Lower Cretaceous Crato Formation of Brazil. A new fossil sawfly species is placed within Tenthredinoidea and characterized by distinctly biflabellate antennae. This morphological feature indicates that long distance mate finding behaviour (as exhibited by males of recent Diprionidae and some Pergidae and Tenthredinidae) was already well established in the Lower Cretaceous. The phylogenetic position of a second fossil, the woodwasp Cratoenigma articulata gen. et. sp.n., is discussed on the basis of relevant thoracic, abdominal and wing venation characters. The latter fossil cannot be placed in any existing superfamily but based on a combination of plesiomorphic, synapomorphic and autapomorphic character states it forms the putative sister group of Xiphydriidae + Euhymenoptera. This would place it well within Unicalcarida, the clade in which the transition from endophytic to a parasitoid lifestyle evolved. These two fossils close significant gaps in the fossil history of Hymenoptera and provide new insights into the Cretaceous diversity of the order.

Why was the genus *Amblyopone* split from the genus *Stigmatomma?* (Hymenoptera: Formicidae) - Mandibular evolution in Dracula ants told from males -

Masashi Yoshimura

California Academy of Sciences, U.S.A.

Ants have a distinct sexual dimorphism. The morphological characters observed in male ants could provide useful hints to determine homologies among strongly specialized characters in worker ants. The workers of Amblyopone and Stigmatomma in the subfamily Amblyoponinae, which are known as "Dracula ants," have a specialized elongate mandible with serriform. On the other hand, the male mandibles in both genera are small and simple. A comparative study of the mandibles among males and workers, and the two genera was carried out to better distinguish Amblyopone and Stigmatomma. The results of this study revealed that the number of mandibular teeth in males is different between Amblyopone and Stigmatomma, and that the difference in mandibular characters reflects the different scenarios for the evolution of the worker mandible in each genus. The difference in the two scenarios is associated with the original open-close position before the mandibles evolved to be longer. Furthermore, Stigmatomma shares the same mandible characters with the other members of the XMAS clade (Xymmer + Mystrium + Adetomyrma + Stigmatomma), which is strongly supported by a recent molecular phylogenetic study (Brady et al. 2006), while Amblyopone does not. These results provide robust evidence that the genus Amblyopone resides outside of the XMAS clade.

Employing polydnavirus genes to uncover cryptic species in Ichneumonoidea

Victoria Pook[1], Michael Sharkey[2]

[1]*University of Kentucky, U.S.A.*, [2]*University of Kentucky, U.S.A.*

Parasitoid wasps are major components of habitat biodiversity and are important in maintaining ecosystem stability. They can also offer an effective, highly specific and environmentally friendly alternative to chemical insecticides. Their success as biocontrol agents depends entirely on our understanding of their biology and phylogenetic relationships -examples of failure where parasitoid wasps have been integrated into a pest management program are all too often the result of incorrect species identification and inadequate knowledge of population genetics. Additionally, correct identification of parasitoid wasps is essential if we are to make accurate estimates of biodiversity in order to locate biodiversity 'hotspots' on which conservation efforts can be focused. I address these issues by examining fast-evolving polydnavirus genes within wasp nuclear DNA. These genes are thought to function to attack the host immune system, and if their variability correlates with host preference they could aid in the identification of cryptic 'specialists' within COI-barcoded 'generalist' species. Correct identification of parasitoid wasps using polydnavirus polymorphism as an indicator of host preference could vastly improve conservation efforts, the success of biocontrol programs and our general understanding of food-web ecology.

Morphology and molecules for the masses: remarkable species diversity in a large and taxonomically challenging genus of ants.

Kathryn Susanne Sparks[1], Andy Austin[2], Alan Andersen[3], Steve Shattuck[4], Steve Donnellan[5]

[1]The University of Adelaide, Australia, [2]The University of Adelaide, Australia, [3]CSIRO, Australia, [4]CSIRO, Australia, [5]South Australian Museum, Australia

Monomorium Mayr (Hymenoptera: Formicidae) is a highly abundant, widespread and diverse genus of ants. Several Australian "species" show considerable morphological and chemical variation, while evidence from ecological and preliminary molecular research suggests significant cryptic diversity. However, rigorous morphological criteria that support separate species have proved difficult. In this study we are using sequence data from multiple loci to generate a phylogeny for the Australian species in order to test the current species group relationships. In addition, we generate hypotheses for species boundaries in the widespread and morphologically diverse seed harvesting M. "rothsteini" complex using a combination of molecular, morphological and distributional data. Preliminary results indicate that the Australian Monomorium species groups, as currently understood, are not supported by the molecular phylogeny and that several groups may be para- or polyphyletic. Our results also provide strong evidence for a large number of unrecognised species in the M. "rothsteini' complex and other morphologically diverse groups and demonstrate the importance of using multiple data sources when making taxonomic decisions.

New insight into an old genus: Revising *Disholcaspis* Dalle Torre & Kieffer, 1910 (Hymenoptera: Cynipidae)

Crystal McEwen
University of Maryland, U.S.A.

As with many Nearctic cynipid genera, the genus Disholcaspis is in desperate need of an updated circumscription. This project seeks to combine a systematic revision of Disholcaspis with an exploration into patterns of host plant usage. Disholcaspis contains over 50 valid species all of which are known to utilize white oaks (Fagaceae, section Quercus) as host plants. Recently described species (from Costa Rica and Panama) have expanded the known distribution of Disholcaspis to a range reaching from Canada to Panama. Many species of cynipids are heterogenetic, with alternating sexual and asexual generations that are not only morphologically distinct but also produce galls on different parts of the same host plant. Disholcaspis wasps are generally only known from their asexually reproducing generations, many of which induce woody stem galls that are often morphologically species specific. The sexual generations within the genus remain mostly unknown, with only those of Disholcaspis quercusvirens (Ashmead) and Disholcaspis cinerosa (Bassett) having been identified, and those of Disholcaspis eldoradensis (Beutenmuller) and Disholcaspis quercusmamma (Walsh & Riley) formally described. The sexual generations have been found to develop within buds and their galls have been found to be morphologically similar across species. Analysis of morphological and molecular data from both generations will aid in clarifying the classification within Disholcaspis as well as give insight into the evolution of plant-insect interactions.

Phylogeny of Dryinidae: Evolution of Fulgoromorpha parasitism

Toshiharu Mita
Tokyo University of Agriculture, Japan

The family Dryinidae comprises parasitoid wasps of Auchenorrhyncha (Homoptera). Females in most subfamilies of Dryinidae have raptorial forelegs that aid in grasping the host insect. The host range is different depending on the taxon. The taxa bearing less developed foreleg parasitize Cicadomorpha, and the taxa bearing more developed foreleg parasitize Fulgoromorpha. Although most members are Fulgoromorpha parasitoids, Gonatopodinae include Cicadelidae parasitoids which have comparatively less developed foreleg, and Bocchinae also parasitize both, but the chela of Bocchus females which parasitize fulgoromorphan family Issidae is quite different from other dryinid taxa. Olmi (1994) explained the evolution of the raptorial foreleg in the view of the activity of host insects, however, the phylogenetic relationship of dryinid taxa has been unclear (Carpenter, 1999). As a result of the cladistic analyses based on 53 morphological characters from 36 species (10 genera, 6 subfamilies), the subfamilies including Fulgoromorpha parasitoids, i.e., Bocchinae, Dryininae and Gonatopodinae clustered single clade. On the other hand, the subfamilies of Cicadomorpha specialists were paraphyletic. Although further study is needed to test the phylogenetic position of Bocchinae, the results supported the synchronous development of foreleg and Fulgoromorpha parasitism. The treatment of some Cicadelidae parasitoids of Gonatopus is still uncertain, but the Fulgoromorpha parasitism is considered as monophyletic. At least (Dryininae + Gonatopodinae) linage can be defined by 6 autapomorphies, and 4 of them are about foreleg morphology. It may explain that the developed foreleg is required because gripping fulgoromorphan insect is more difficult than Cicadomorpha.

Comparative mitochondrial genomics of Hymenoptera

Shu-jun Wei[1], Xue-xin Chen[2], Bao-cai Shi[3], Ya-jun Gong[4]

[1]Beijing Academy of Agriculture and Forestry Sciences, China, [2]Beijing Academy of Agriculture and Forestry Sciences, China, [3]Beijing Academy of Agriculture and Forestry Sciences, China, [4]Beijing Academy of Agriculture and Forestry Sciences, China

Animal mitochondrial genes and genomes have been widely used in population genetics, species identification, phylogenetic studies and evolution. Recent years, many studies focused on the comparative and phylogenetic studies of insect mitochondrial genomes. Hymenoptera, as one of the most species richness and diverged group, their mitochondrial genomes show unique features compared with those of other insects. Presently, 32 mitochondrial genomes have been sequenced from Hymenoptera, representing 15 families. There are five characteristics in the mitochondrial genomes of Hymenoptera: (1) high A+T content in most species of Apocrita; (2) reversal of strand asymmetry in the Family of Braconidae; (3) extremely fast on the evolutionary rate compared with nuclear genes in some lineages; (4) frequent and evolutionary independent rearrangement of tRNA gens; (5) accelerated protein-coding gene rearrangement in some lineages. The phylogenetic study using complete mitochondrial genomes sequence indicate a basal position of Hymenoptera in holometabolous insect and novel phylogenetic relationships with this order.

A molecular phylogeny of Bethylidae (Hymenoptera: Chrysidoidea) based on mitochondrial and nuclear genes

Jongok Lim[1], Sunghoon Jung[2], Celso Oliveira Azevedo[3], Hyojoong Kim[4], Il-Kwon Kim[5], Seunghwan Lee[6]

[1]Korea National Arboretum, Republic of Korea, [2]University of California, Republic of Korea, [3]Universidade Federal do Espirito Santo, Brazil, [4]Kunsan National University, Republic of Korea, [5]Korea National Arboretum, Republic of Korea, [6]Seoul National University, Republic of Korea

A molecular phylogeny of the family Bethylidae (Hymenoptera: Chrysidoidea) was conducted based on a total of 49 species consisting 43 ingroup species of 19 genera and 6 outgroup species by using 4 molecular markers, mitochondrial 16S rRNA, CytB, and nuclear 18S rRNA, 28S rRNA genes. Data were analysed using maximum likelihood (ML), parsimony and Bayesian inference (BI) phylogenetic frameworks. As results, followings are confirmed: (1) sister group relationships of Chrysididae and Bethylidae; (2) monophyly of Bethylidae; (3) monophyly of Bethylinae, sistered to the rest of Bethylidae; (4) monophyly of Epyrinae is not supported, as Epyrinae is divided into two separated clades, Epyrini and Sclerodermini; these tribes sistered to subfamilies, Pristocerinae and Mesitiinae, respectively; (5) monophylies of the other subfamilies, (e.g. Pristocerinae). These results are largely congruent with former hypotheses based on morphological and molecular data with respect to the monophyly of various subfamilies and tribes. Some phylogenetic relationships are also found at lower level: (1) a complex clade consisting of three genera, Acrepyris, Apenesia and Pristocera; (2) Laelius and Formosiepyris is more close to Holepyris than Epyris; (3) Sclerodermini of Epyrinae is the sister group of a clade of Pristocerinae+Epyrini. Based on these results, we discussed on the phylogenetic relationships of Bethylidae comparing to morphological and traditional classifications.

Morphometric and landmark based variations of *Apis mellifera* L. wings in the forest vegetation zone of Nigeria

Akeem Abolade Oyerinde[1], Micheal Chidozie Dike[2], Olalekan Banwo[3], Lucius Joseph Bamaiyi[4], Rabiu Saliu Adamu[5]

[1]university of abuja, Nigeria, [2]Ahmadu Bello University, Nigeria, [3]Ahmadu Bello University, Nigeria, [4]Ahmadu Bello University, Nigeria, [5]Ahmadu Bello University, Nigeria

212words There are several different methods of classifying insect. The technique of using wing landmarks and morphometric features to discriminate insect population into species and specify the variations in the varieties within the intra specific group was used to classify Apis mellifera kept in beekeeping practice in the forest vegetation zone of Nigeria into morphoclusters. The multivariate morphometric data obtained was analysed with parametric statistic tools of mean, standard deviation and standard error. The distribution and relation between them were subjected to two step cluster analysis. Morphoclusters means were presented in centroids and also the simultaneous confidence intervals (95%) of means values of wing morphometric and landmarks were expressed. Varieties of Apis mellifera found in this study formed four distinct morphoclusters based on wing landmarks and morphometric. Osun State recorded morphoclusters 1 and 2 while Ebonyi and Oyo States had morphoclusters 3 and 4 respectively. 20 landmarks that occurred on the forewing of morphoclusters 1, 3 and 4 were the same while the record of 19 landmarks observed in honeybees of morphoclusters 2 was different from the existing records. Based on our findings in this study it is reliable to use the variations on the wing landmarks and morphometric of honeybee workers to group Apis mellifera in Nigeria into varieties of existing species.

Survey on biology and distribution of *Biorhiza pallida* Olivier (Hymenoptera: Cynipidae) and identification of its parasitoids in West-Azerbaijan, Iran

Abbas Hosseinzadeh[1], Zahra Hashemi Khabir[2], Negar Alioghli[3], Nouraddin Shayesteh[4]

[1]Mahabad Branch, Islamic Azad University, Iran, [2]Agricultural and Natural Resources Research Center of West-Azerbaijan province, Iran, [3]Plant Pests and Diseases Research Laboratory of East-Azerbaijan Province, Iran, [4]Mahabad Branch, Islamic Azad University, Iran

The species named oak apple gall wasp belongs to family Cynipidae and tribe Cynipini. From 2009 to 2010, field samplings of produced galls on Quercus infectoria Olive. were conducted and collected galls were identified with recordings of date and the location of collection. The galls were transferred into plastic container dishes in order to check emergence and for identification of natural enemies, especially parasitoids. The gall produced by Biorhiza pallida was rounded and looked like apple fruit. The B. pallida galls were bright-green with bright-red surface and were produced on the branches of Q. infectoria. This gall was multichambered and was produced by sexual form of this species in the spring (May and June). The first galls emerged in mid-May and maximum growth of galls occurred at the end of June and at that time diameter of galls was 10?20 mm. Asexual form of B. pallida produced the galls that looked like potato on root of Q. infectoria in the summer. Distributions of the produced gall by B. pallida were in locations such as Ghabre-hossein, Banokhalaf, Zamziran, Rabat and Mirabad areas. The most important point about these regions was that their climates were the same. The identified parasitoids of B. pallida were: Torymus erucarum, Torymus flavipes, Cecidostiba fungosa, Sycophila biguttata, Sycophila variegate, Ormyrus pomaceus, and Mesopolobus sp.

Phylogenetic relationships of Agaristinae (Lepidoptera: Noctuidae) based on adult morphology, with special reference to the biogeography of "sound-producing clades" and the evolution of diurnality

Wu Shipher[1], Shiuh-Feng Shiao[2], She-Horn Yen[3]

[1]National Taiwan University, Taiwan, [2]National Taiwan University, Taiwan, [3]National Sun Yat-sen University, Taiwan

The Agaristinae represents a large subfamily of Noctuidae, consisting of 127 genera and about 500 species ranging throughout all the major continents except Antarctica and Greenland. The adults of this subfamily are either diurnal, crepuscular, or nocturnal, and characteristic with bright and contrasted colouration that is considered relevant to aposematism or mimicry, both unusual in Noctuidae. The larvae of Agaristinae are also bright-coloured and feed on several plant families that contain alkaloid secondary compounds. The male of several genera possess an exaggerated forewing tymbal structure which is used for sound production, and distribution of these sound-producing genera seems to imply a Gondawanan origin. In contrast with its high diversity, the studies on Agaristinae systematics and biology are fairly rare. In the present study, we present the first phylogenetic study of Agaristinae to address several questions: (1) is Agaristinae a monophyletic group? (2) is the classification system proposed by Kiriakoff (1976) approved by modern method? (3) if the taxa having swollen forewing costal margin are closely related and suggest any biogeographical significance? The phylogenetic pattern shows that Agaristinae of the current concept is monophyletic, but adult morphology may have little help in resolving the relationship because both the male and female genitalia are relatively conservative across . The "chorotaxa" system proposed by Kiriakoff, therefore, cannot be rejected due to the poor resolution of the phylogeny. Meanwhile, the taxa having protruded forewing do not constitute a monophyletic clade, so this character might have evolved independently in different continents.

Early amphiesmenopteran and lepidopteran fossils from the mid-Jurassic Jiulongshan formation of China reveal their early evolution and diversity

Jae-Cheon Sohn[1], Weiting Zhang[2], Conrad Labandeira[3], Chungkun Shih[4], Donald Davis[5], Dong Ren[6], Charles Mitter[7], Oliver S. Flint, Jr.[8]

[1]University of Maryland, U.S.A., [2]College of Life Sciences, Capital Normal University, China, [3]National Museum of Natural History, Smithsonian Institution, U.S.A., [4]College of Life Sciences, Capital Normal University, China, [5]National Museum of Natural History, Smithsonian Institution, U.S.A., [6]College of Life Sciences, Capital Normal University, China, [7]University of Maryland, U.S.A., [8]National Museum of Natural History, Smithsonian Institution, U.S.A.

The Jiulongshan Formation of Daohugou Beds is situated along the provinces of western Liaoning and eastern Inner Mongolia in China. This well known deposit has yielded an abundant, diverse and exquisitely-preserved assemblage of terrestrial fossils that provide a unique window for examining in particular the morphology and ecology of Mesozoic insects. The insect material at Daohugou especially has been important for furthering knowledge about the holometabolan lineage Amphiesmenoptera whose early evolution remains poorly known because of their depauperate Mesozoic fossil record. We have found approximately 14 specimens at Daohugou that can be assigned to the Amphiesmenoptera, representing the common ancestral stock preceding the complete divergence of Lepidoptera and Trichoptera, or otherwise are referable to the Trichoptera and basalmost Lepidoptera. We have assessed the morphologies of the Daohugou specimens and their affinities with other basal amphiesmenopteran families from the Jurassic, such as Necrotauliidae, Archaeolepiidae, Mesokristenseniidae and Eolepidopterigidae. In addition, we have explored the process of how the lepidopteran apomorphies may have evolved. The new fossils provide the earliest records of lepidopteran mandibulate mouthparts and possible internal feeding within amphiesmenopteran/lepidopteran lineage, hinting their ecological diversity. The mid-Mesozoic diversity of the Amphiesmenoptera and Lepidoptera is comparable to other insect lineages from Jiulongshan Formation whose abundance may be directly related to preservational potential, and thus taphonomic bias.

Discovery of a new species of the genus *Roeslerstammia* Zeller (Lepidoptera, Roeslerstammiidae) from China, with notes on the identity of two Indian species described by Meyrick

Toshiya Hirowatari[1], Guohua Huang[2]

[1]*Osaka Prefecture University, Japan,* [2]*Hunan Agricultural University, China*

The genus Roeslerstammia includes four species: Roeslerstammia erxlebella (Fabricius, 1787) and R. pronubella (Denis & Schiffermuller, 1775) from Europe to Japan, and R. metaplastica Meyrick, 1921 and R. hemiadelpha Meyrick, 1922 from Punjab, India. Although some reports on morphology and biology of the former two species have been published, nothing has been known about the two Indian species described by Meyrick since the original description, and no species has yet been recorded from China. In May, 2009, we collected an unknown species of microlepidoptera at Tianpingshan, in the northern part of Hunan Province, China. As a result of examination, we confirmed the following characters which are diagnostic in Roeslerstammiidae (Kyrki, 1983): forewing R5 reaching to costa, tegumen bilobed, gnathos present, valva with a small pad of long hair scales on the outside near the base, aedeagus consisting of a slender curved tube. In the species collected in China, there is a triangular white marking at costa and the shape of the aedeagus and valva in the male genitalia is unique, which indicates that it represents a new species belonging to Roeslerstammia. On the basis of material deposited in BMNH (London), the two Indian species described by Meyrick are reviewed for the first time since the original description and the identity of the two species is also commented on.

Review the fauna of Pyraustinae (Lepidoptera, Crambidae) in NE China

Mu-jie Qi[1], Cheng-de Li[2], Hui-lin Han[3], Yang-Seop Bae[4]

[1]University of Incheon, China, [2]Northeast Forestry University, China, [3]Northeast Forestry University, China, [4]University of Incheon, Republic of Korea

Pyraustinae are one of the subfamily of Crambidae belong to Lepidoptera, which comprises 7381 species in the world (Heppner, 1991). They can be identified by the following characters: Chaetosema absent, labial palpus and proboscis well developed, maxillary palpus filiform or brush-shaped; forewing with R3 and R4 stalk at base, or R2, R3 and R4 stalked, but R5 single; Cup absent, 2A and 1A form a loop; hindwing Sc+R1 stalked with Rs; male genitalia with gnathos absent or rudimentary. The Northeast region of China comprises Heilongjiang, Jilin, Liaoning Province, and Inner Mongolian, The length of NE China from south to north is 1600 km, and the total area is 1,241,400 km2, it includes Greater and Lesser Xing'an Mountains, Changbai Mountains, Zhangguangcailing Mountains, and Laoyeling Mountains. NE China is an important area for forestry and agriculture, many diseases and pests occurred every year. So the research on biodiversity of NE China is of great significance in systematic study and the basis for pests control in NE China. Up to now,there are about 700 Pyraustinae species in China (Li houhun, 2009), but only a few species reported from northeast. Accordingly, it is of great importance to survey the Pyraustinae in NE China. In this study, we indentified 102 Pyraustinae species from NE China, of them, 3species are the first time reported in China, and 11 are the first time reported in Heilongjiang Province, 16 are the first time reported in Jilin Province, and 21 are the first time reported in Liaoning Province.

Three new species of Gracillariidae (Lepidoptera) from China and Japan, with descriptions of the pupal morphology of the genera *Eumetriochroa, Guttigera* and *Metriochroa*

Shigeki Kobayashi[1], Guohua Huang[2], Toshiya Hirowatari[3]
[1]*Osaka Prefecture University, Japan,* [2]*Hunan Agricultural University, China,* [3]*Osaka Prefecture University, Japan*

Adult Oecophyllembiinae sensu Kumata (1998) are some of the smallest leaf-mining gracillariid subfamilies, with a wing expanse of only 5-10 mm. Recent authors (Vari et al. 2002; De Prins & De Prins, 2005, 2012) treated Oecophyllembiinae as a synonym of Phyllocnistinae. Because the position of this sister-group remains unclear, we follow Kumata (1998) in placing six genera in Oecophyllembiinae, and Phyllocnistis as the sole member of the Phyllocnistinae. In China, we recorded two Oecophyllembiinae species: Corythoxestis sunosei (Kumata, 1998) and Eumetriochroa hederae Kumata, 1998, and described the pupae of the genera Corythoxestis and Eumetriochroa for the first time (Kobayashi et al., 2011). We found three diagnostic differences in them from other genera of Oecophyllembiinae and Phyllocnistis. In the present study, as a result of our field work in China and Japan, we recognize three new Oecophyllembiinae species, among which are included a Metriochroa sp. feeding on Symplocaceae and Eumetriochroa sp. and Guttigera sp. feeding on Araliaceae. Pupae of six species of the genera Eumetriochroa, Guttigera and Metriochroa are described for the first time. We also report life histories and new host plants of Corythoxestis sunosei from Japan. Pupae of Eumetriochroa species have paired setae on the clypeus, and Oecophyllembiinae species have a cremaster with two pairs of caudal processes. The pupal characters described above may provide a useful diagnosis between species of Oecophyllembiinae genera and Phyllocnistis.

Overview of moths diversity (Lepidoptera) in the Northern Part of Vietnam

Yang-Seop Bae[1], Xuan Vi Le[2], Kyu-Tek Park[3], Jong-Gyun Park[4], Nha Van Pham[5], Cuong Nhu Nguyen[6], Vuong Thi Pham[7]

[1]University of Incheon, Republic of Korea, [2]University of Incheon, Vietnam, [3]The Korean Academy of Science and Technology, Republic of Korea, [4]Kyungpook National University, Republic of Korea, [5]Vietnam Academy of Agricultural Sciences, Vietnam, [6]Vietnam Academy of Agricultural Sciences, Vietnam, [7]Vietnam Academy of Agricultural Sciences, Vietnam

The fauna of the Moths in Vietnam is poorly known. The first data for moths of Vietnam was initiated by French entomologist, de Joannis (1900, 1912, 1928-1929), reported 527 species from the northern part of Vietnam. Kitching & Spitzer (1995) reviewed 117 species of Sphingidae, 271 species of Noctuidae were listed by Hungarians (Ronkay, 1989; Hreblay & Ronkay, 1999; Hreblay & Ronkay, 2001). In 2000, 290 species of Notodontidae, 98 species of Lasiocampidae and 153 species of Limacodidae were reported (Zolotuhin, V.V & T.J. Witt, 2000). Kuznetzov (2000) annotated a list of 208 tortricid species from Vietnam. Recently, 33 species of tortricidae were described as new to science by Razowski (2008 & 2009). Besides, moths of Vietnam was also reviewed or described by other entomologists; Prout (1921), Candeze (1927), Boursin (1928, 1940), and Lamee & Tam (1950). One of the recent Vietnamese publications on moths of agricultural pests was published by the National Institute for Plant Protection (1977-1978 & 1997-1998) with 24 species of Noctuidae, 77 species of Pyralidae, and some other moths were listed. In the present study, from 2004 to 2010 with 14 times of survey in the Northern part of Vietnam have been done by Vietnamese and Korean entomologist. Totally, 564 species of Noctuidae, 201 species of Pyralidae, 23 species of Lecithoceridae, and 28 species of Sphingidae were recorded (Park et al., 2007). Besides, more than 120 species of Tortricidae were recognized from current study.

Systematics of Asian skippers (Lepidoptera: Hesperiidae): What have been known and what should be done.

Hideyuki Chiba

Freelance (Research Associate, Bishop Museum), Japan

The taxonomy of Asian skippers has been relied largely on a series of catalogues compiled by Brigadier W. H. Evans. Although, numerous new taxa have been added and some parts of Evans' work have been revised, his catalogue still plays a major role in the study of Asian skippers. Limitation of Evans' 6-volume work is its separation into 3 geographic regions, namely Africa, Eurasia & Australia, and America. The relationship of taxa and their pattern of distribution across these areas are not fully discussed. Taxonomic revisions of the group including Asian and African taxa are being progressed, and many, if not all, Afro-Asian genera are revealed to be polyphyletic. Current development in information technology changed such a research from a taxonomist's solitary work to collaborative research involving people far away. Recently, a framework of higher taxonomic category based on molecular and morphological phylogeny is settled. The status of the Asian skippers is not drastically altered in this new framework. However, tribal level relationship, or genus group in Evans' sense, of the subfamily Hesperiinae is not resolved satisfactorily, leaving many taxa in Incertae Sedis. Molecular data are being accumulated, notably in DNA barcoding locus. Availability of fresh specimens is the major limiting factor. Local checklists have been updated extensively. However, considerable places such as Sumatra and Java have been left behind. Evans' catalogue is unsatisfactory as an identification tool, and reliable taxonomic keys are needed. The genus Choaspes (Coeliadinae) is employed as a model case to demonstrate the current progress.

How could we solve taxonomic conflicts between traditional data and DNA barcodes in the Korean Butterflies?

Tae Hwa Kang[1], Tae Man Han[2], Young Bo Lee[3], Sung Soo Kim[4], Sang Hyeon Lee[5], Jong Chel Jeong[6], Sang Kyu Son[7], Hae Chul Park[8]

[1]National Academy of Agricultural Science, Republic of Korea, [2]National Academy of Agricultural Science, Republic of Korea, [3]National Academy of Agricultural Science, Republic of Korea, [4]Research Institute for East Asian Environment and Biology, Republic of Korea, [5]Sunyou Co., Republic of Korea, [6]Seodaemun Museum of Natural History, Republic of Korea, [7]The Lepidopterists' Society, Republic of Korea, [8]National Academy of Agricultural Science, Republic of Korea

We analyzed 921 DNA barcodes (4.6 samples per species) for 202 resident Korean butterfly species. Most samples were collected from 2009 to 2011, and we obtained 28 samples of 11 species from the adjacent regions such as Russia, North Korea, and Japan for comparative analysis with the closely related species. The obtained samples were morphologically identified based on wing patterns. In a result, genetic divergence to the nearest-neighbouring taxon varied from 0 to 28.2%, with an average of 13.4 per cent. The neighbour joining (NJ) tree profile showed that sequence data for 185 (91.6%) of the 202 species formed distinct barcode clusters, allowing for their unambiguous identification. However, the rest 17 species were not matched for the traditional taxonomy. They consist of two species pairs (2.0%) that separated from each species by less than 1% branch length, two species pairs and one triple species pair (3.4%) that were paraphyletic, three species (3.0%) that were polyphyletic with sharing barcodes, and four clusters that separated from existing species by deep branch length and barcoding gap. These ambiguous cases could not be identified by only using DNA barcodes and wing patterns. Therefore, we tried to identify them using other taxonomic methods such as examination of aedeagal characters, RAPD, analysis of other gene regions, and comparison of ecological traits for each species.

Systematic study on the genus *Promalactis* Meyrick (Lepidoptera: Oecophoridae)

Sora Kim[1], Kyu-Tek Park[2], John B. Heppner[3], Seunghwan Lee[4]

[1]Seoul National University, Republic of Korea, [2]The Korean Academy of Science and Technology, Republic of Korea, [3]Florida Museum of Natural History, U.S.A., [4]Seoul National University, Republic of Korea

The genus Promalactis Meyrick 1908 is one of the largest genera of the family Oecophoridae (Lepidoptera), comprising more than 150 species worldwide with a great diversity in the Palaearctic and Oriental regions, especially in Southeast Asia (Kim et al. 2010). More than 90 species have been reported from eastern Asia, approximately 40 species are known from Southern Asia (Kim et al., 2012). They are characterized by brownish yellow to yellowish brown ground color with variable white marking, such as oblique, median, costal, or apical spots. We focused on that Promalactis species having variable genitalia can be grouped into same or similar wing pattern. To examine the availability of wing pattern as a key character for species grouping, we analyzed the morphological data, wing pattern forms, and molecular data based on the mitochondrial COI gene. Additionally, a phylogenetic relationship within the family was conducted, based on mitochondrial COI and 16s rRNA genes, and nuclear 28s rRNA and 18s rRNA genes. As a result, we confirmed that the groups of genetically close Promalactis species on the mitochondrial COI correspond to the groups with similar wing patterns, and also grouped as the monophyletic clades. Based on these results, we propose a taxonomic importance of wing patterns as key character for the species-groups, and a new genus by unique wing pattern for Promalactis polyspina.

Does mimetic coloration of the model always evolve earlier than that of mimic? A case study based on the "Euploea mulciber mimicry complex" in SE Asia

Chia-Hsuan Wei[1], Li-wei Wu[2], Yu-feng Hsu[3], Shen-Horn Yen[4]

[1]National Sun Yat-Sen University, Taiwan, [2]National Taiwan Normal University, Taiwan, [3]National Taiwan Normal University, Taiwan, [4]National Sun Yat-Sen University, Taiwan

In a mimicry system, the model possessing a remarkable pattern and secondary defense mechanism simultaneously is generally expected to have evolved earlier than the co-mimics, which benefit from the resemblance of the colour pattern. Previous studies have demonstrated that while a mimetic pattern arose from a non-mimetic pattern, population differentiation or speciation was usually attended. The relative divergence times among independent co-mimicking lineages carrying multiple defense mechanisms, however, have rarely been explored. In the present study, we focused on the "Euploea mulciber" mimicry complex characterized by having sexually dimorphic wing patterns that are perfectly matched between both sexes of co-mimicking species, which have sympatric polymorphic forms, various secondary defense mechanisms and a wide distribution range throughout E. Himalaya, Indochina and Sundaland. Sequence information from multiple genes were extracted to reconstruct the individual phylogenies of four lepidopteran groups, Euploea, Elymnias (Nymphalidae), Papilio (Chilasa) (Papilionidae), and Cyclosia (Zygaenidae). Estimates of divergence times show that the mimicry complex might have formed since middle Miocene. The estimated divergence times of Cyclosia (with chemical defense based on cyagnoglocosides) and Elymnias (without chemical defense) are later than that of Eu. mulciber. Either the genus Chilasa or the mimicking Ch. paradoxa has evolved earlier than Eu. mulciber. The results suggest that species with non-mimetic pattern can involve earlier than the model, but the mimetic pattern arises subsequently.

Taxonomical traits of native population of *Antheraea assamensis* Helfer (Muga silkworm) of Assam, India

Ramesh Nath[1], Dipali Devi[2]

[1]Dhing College, India, [2]Institute of Advanced Study in Science and Technology, India

The sericigenous Saturniid Antheraea assamensis Helfer, 1837, (muga silkworm) having the lowest chromosome number n=15 is known as the ancestral form of the genus Antheraea. This insect is exclusively confined to the Brahmaputra valley of Assam and some parts of neighboring states of NE region of India due to its unique ecological niche. Although it is a monotypic species, it has four distinct larval color morphs, namely green, blue, orange and yellow and these are non diapausing multivoltine in nature. A diapausing wild morph is also found in the forests of this region. Lack of systematic study on taxonomical trait of this natural population instigated to study the distinguished morphological characters in egg, larva, cocoon and moth stages. During the study negligible variation was observed among the color morphs and there is no impact of larval coloration on cocoon characters. However significant variation was observed in respect of voltinism, geotropism, chorion structures, larval tubercle, setae number, cocoon characters, wing pattern, male genitalia and antennae between the color morphs and the wild morph. Based on this study the three color morphs viz. green ,blue and orange could be clubbed together and the wild morph remains separately .It is expected that this study will help in designing the breeding programme for improved hybrid vigor as the population is suffering from inbreeding depression. It will help in maintaining the stable and sustainable population, thereby saving the precious germplasm of A. assamensis from extinction.

Arctiid Diversity from India

Jagbir Singh
Punjabi University, India

The moths belonging to family Arctiidae of order Lepidoptera is an attractive and fascinating group of insects in terms of species diversity and also of immense economic importance. These moths are colorful creatures, often with moderately broad wings which are conspicuously spotted, banded or otherwise marked with bright colors. Over 4000 species are known from the globe and group is well represented in nearly all zoogeographical regions but attains its greatest development in the tropics. Arctiid moths are defined principally by the presence of tymbal organ on metaepisterum and pre- spiracular counter tympanal hood. Studies on taxonomy of Indian Arctiid moths is in progress for the last two decades. As many as 512 species of these insects are known from India and out of these 356 species have been collected, studied and authentically identified. Taxonomic revision of Indian Arctiidae has brought many new taxa to light. Collection-cum-survey tours have been conducted in the far flung localities of India to study these beautiful moths. External gentialic structures of all the studied species have been dealt with and illustrated in detail. A lot of nomenclature changes have been suggested for the future workers. The present communication deals with Arctiid diversity from India and the importance of external genitalic structures in the taxonomy of this family has been highlighted.

Composition of subfamily Tortricinae (Lepidoptera, Tortricidae) from Northern Part of Vietnam

Xuan Vi Le[1], Thi Vuong Pham[2], Do-Young Chae[3], Yang-Seop Bae[4]

[1]University of Incheon, Vietnam, [2]Vietnam Academy of Agricultural Sciences, Vietnam, [3]University of Incheon, Republic of Korea, [4]University of Incheon, Republic of Korea

Tortricinae is the largest of three subfamilies in the Tortricidae and was divided into 11 tribes (Horak and brown, 1991). Tortricinae can be distinguished from other subfamilies by the two rings of scale on each antenna segment, and the caulis articulated with the juxta by a short membrane. About 1010 named species are presenting in Palaearctic region (Razowski, 2008) including 382 species in Europe (Razowski, 2003), 260 species were recorded from South East Asia (Robinson, Tuck and Shaffer, 1994). The fauna of Tortricinae in Vietnam is poorly known even some expeditions were previously done by some foreign entomologist. One of the recent Vietnamese publications on moths of agricultural pests was published by the National Institute for Plant Protection (1977-1978 & 1997-1998), only seven Tortricidae species were recorded. In the year, 2000 Kuznetzov annotated a list of 208 tortricid species from Vietnam. Recently, more than 80 species belong to Tortricinae are announced from 2008 to 2009 by Razowski. Of them, 33 species were described as new to science. At present, the tortricid fauna of Vietnam is estimated approximately 315 species (Svetlana V. Nedoshivina, 2010). From the results of the study on subfamily Tortricinae in Northern part of Vietnam, totally, 28 species of 13 genera are recognized, but only 9 species were previously recorded. Besides, some unidentified species are waiting for further study. The materials examined are based on the collection of University of Incheon, which were collected from 2004-2010 in the Northern part of Vietnam by Vietnamese and Korean entomologist.

Finding the sister group of Cryptocercidae + Isoptera: A combined molecular and morphological phylogeny of Dictyoptera

Marie Djernaes[1], Klaus-Dieter Klass[2], Paul Eggleton[3]

[1]Natural History Museum, United Kingdom, [2]Senckenberg Natural History Collections, Dresden, Germany, [3]Natural History Museum, United Kingdom

Recent phylogenetic studies have established that termites belong within the cockroaches as sister to Cryptocercidae. Cryptocercus shares several important behavioural traits with termites, thus we need to understand the phylogenetic position of Cryptocercidae + Isoptera to determine how these traits evolved. However, placement of Isoptera + Cryptocercidae is still uncertain. Suggested sister groups include Polyphagidae + Lamproblattidae, Polyphagidae + Nocticolidae, Blattidae, Tryonicidae, Blattidae + Tryonicidae, and all other Dictyoptera. None of the possible sister groups are known to share more similarities in lifestyle with Cryptocercidae + Isoptera than the others; e.g. representatives of all have been found in rotting wood. Previous phylogenetic studies of Dictyoptera have been either molecular or morphological. The only exception is Ware et al. (2008) using already published data resulting in a large proportion of missing data, and no targeted taxon sampling. Despite the large number of studies, no consensus has been reached on the deep splits within Dictyoptera. The present study includes all the previously suggested sister groups of Isoptera + Cryptocercidae as well as other potentially important taxa such as an Australian polyphagid which form colonies in wood cavities, but have never been included in phylogenetic studies. We combine molecular and morphological characters as well as a large outgroup sampling to produce a stable phylogeny of Dictyoptera. Finding the sister group of Cryptocercidae + Isoptera offers insight into the development of an ecologically essential group which can also serve as a model for development of eusociality.

Molecular and phylogeographic analysis of the relict dragonflies of *'Epiophlebia'* (Insecta: Odonata)

Sebastian Buesse[1], Philipp von Grumbkow[2], Kazunori Yoshizawa[3], Sonja Wedemann[4], Thomas Hoernschemeyer[5]

[1]Georg-August-University Goettingen, Germany, [2]Georg-August-University Goettingen, Germany, [3]Graduate School of Agriculture, Hokkaido Univerity Sapporo, Japan, [4]Senckenberg, Germany, [5]Georg-August-University Goettingen, Germany

The relict dragonflies of 'Epiophlebia' show several peculiar traits, e.g. in their disjunct distribution in the Eastern Palearctic and Oriental regions as well as in the unique combination of morphological characters, which are otherwise characteristic of dragonflies or damselflies. The three extent species 'Epiophlebia superstes' Selis, 1889, 'Epiophlebia laidlawi' Tillyard, 1921 and the lately discovered 'Epiophlebia sinensis' Li & Nel, 2011 are the only recent representatives of these strongly cool-adapted dragonflies. Our results gain insights into the interspecific similarities in the DNA of the 'Epiophlebia'-species, which is significantly higher than between other closely related species of Odonata. It resembles the degree of similarity found in different populations of the same species. Furthermore, the morphological differences between of 'E. laidlawi' and 'E. superstes' are minor and might not be sufficient for taxonomically maintaining three species in the genus 'Epiophlebia'. Therefore, we float a suggestion that the occurrences of 'Epiophlebia' in the Himalaya probably are populations of 'Epiophlebia superstes'. Such a disjunct distribution reflect historical events, and a major goal of research is to deduce which events were responsible for the given distribution pattern. The minor differences in the DNA sequences indicate that the extant population of 'Epiophlebia' had a significant genetic exchange until quite recently. The last possibility for such an exchange most likely existed during the last ice age when the sea level was at its lowest approximately 20000 year ago. At this time the area occupied by 'Epiophlebia' probably was much larger, encompassing and connecting its extant populations.

The evolution of insect flight

Thomas Hoernschemeyer
University Goettingen, Germany

The ability to fly is essential for the evolutionary success of the winged insects, which make up more than half of all known species. Nevertheless, the origin of insect flight, its morphological foundations and the subsequent evolutionary events are still not well understood. One aspect that probably contributes significantly to our problems in deciphering the processes in the evolution of insect flight is the considerable age of this trait. Already as early as in the middle of the Carboniferous, approximately 324 million years ago, pterygote insects with a fully developed flight apparatus existed. This indicates that the group had its origin significantly earlier, perhaps in the lowest Carboniferous or even in the upper Devonian. Investigations of the morphology of extant pterygotes, of their embryological development and of insect fossils had previously resulted in several contradicting hypotheses on different aspects of the origin and evolution of insect flight. Now, our recent comprehensive studies of the flight apparatus morphology, including musculature and sclerites, of numerous representatives of Ephemeroptera, Odonata and Neoptera, supplemented with investigations of the ontogenetic development of these structures and combined with the reanalysis of insect fossils allow for new interpretations of several aspects in the sequence of events of the evolutionary origin and development of insect flight.

A preliminary phylogeny of Pyrgomorphidae (Orthoptera: Caelifera) based on morphological characters

Ricardo Marino-Perez[1], Hojun Song[2]

[1]*University of Central Florida, U.S.A.*, [2]*University of Central Florida, U.S.A.*

Pyrgomorphidae is the sole member of the superfamily Pyrgomorphoidea within Acridomorpha (Orthoptera: Caelifera). Commonly known as the gaudy grasshoppers, pyrgomorphs are easily diagnosable by a groove in the fastigium and phallic structures, but there are great morphological variations within the family that has led to 140 years of taxonomic instability. Currently the family is composed by 477 species distributed mainly in the Old World as well as Mexico, South America, and Australia and is divided in two subfamilies, Pyrgomorphinae and Orthacridinae, which include 31 tribes and 5 genera incertae sedis. The most recent phylogenetic analysis based of mitochondrial genome data places Pyrgomorphidae as sister to Acridoidea. In this study, we reconstruct a preliminary morphological phylogeny of Pyrgomorphidae based on 40 ingroup genera representing 10 of the 13 tribes from the subfamily Orthacridinae and all the 18 tribes from the subfamily Pyrgomorphinae. This is the first attempt to obtain a comprehensive phylogeny of the family that will provide new insight into understanding the evolution of this interesting family.

Koenig, Germany

Holometabola (= Endopterygota) is one of the most species-rich lineages of living organisms. Extensive efforts have been made to reconstruct its phylogeny. However, the evolution of the group is far from being completely understood. For example, the phylogenetic relationship of twisted-wing parasites (Strepsiptera) to other endopterygote insects has proven notoriously difficult to resolve ("The Strepsiptera problem"). To infer a robust backbone tree of the holometabolous insect orders, we (1) collected comprehensive transcriptome data, (2) sequenced the genome of a twisted-wing parasite, and (3) compiled extensive morphological data sets. The transcriptome data include for the first time representatives of all recognized holometabolous insect orders. In all major lineages we selected species for sequencing that diverged early in the evolution of each order and that can be assumed to be plesiomorphic in many aspects. The genome sequence data of Mengenilla (Strepsiptera) include more than 1.8 million sites of orthologous and inparalogous genes plus sequence-independent genomic meta-characters, such as gene order and the position of introns within genes. The morphological data encompass characters of different life stages and body parts, including many internal features. The analyses of these data allowed a solid reconstruction of the interordinal relationships of holometabolous insects, including the clarification of the phylogenetic origin of the Strepsiptera. We found overwhelming support for Strepsiptera being the sister group of monophyletic beetles. The inferred phylogenetic tree of holometabolous insects facilitates a better understanding of the evolution of morphological characters and of developmental and ecological traits.

Early evolution and historical biogeography of fishflies (Megaloptera: Chauliodinae): Implications from a phylogeny combining fossil and extant taxa

Xingyue Liu[1], Yongjie Wang[2], Chungkun Shih[3], Dong Ren[4], Ding Yang[5]

[1]China Agricultural University, China, [2]Capital Normal University, China, [3]Capital Normal University, China, [4]Capital Normal University, China, [5]China Agricultural University, China

Fishflies (Corydalidae: Chauliodinae) are one of the main groups of the basal holometabolous insect order Megaloptera, with ca. 130 species distributed worldwide. A number of genera from the Southern Hemisphere show remarkably disjunctive distributions and are considered to be the austral remnants or "living fossils" of Gondwana. Hitherto, the evolutionary history of fishflies remains largely unexplored due to limited fossil record and incomplete knowledge of phylogenetic relationships. Here we describe two significant fossil species of fishflies, namely Eochauliodes striolatus gen. et sp. nov. and Jurochauliodes ponomarenkoi Wang & Zhang, 2010 (original designation for fossil larvae only), from the Middle Jurassic of Inner Mongolia, China. These fossils represent the earliest fishfly adults. Furthermore, we reconstruct the first phylogenetic hypothesis including all fossil and extant genera worldwide. Three main clades within Chauliodinae are recognized, i.e. the Dysmicohermes clade, the Protochauliodes clade, and the Archichauliodes clade. The phylogenetic and dispersal-vicariance (DIVA) analyses suggest Pangaean origin and global distribution of fishflies before the Middle Jurassic. The generic diversification of fishflies might have happened before the initial split of Pangaea, while some Gondwanan-originated clades were likely to be affected by the sequential breakup of Pangaea. The modern fauna of Asian fishflies were probably derived from their Gondwanan ancestor but not the direct descendents of the Mesozoic genera in Asia.

Phylogenetic analysis of Panorpidae (Mecoptera) with special reference to the female genital plates

Na Ma[1], Baozhen Hua[2]

[1]Northwest A & F University, China, [2]Northwest A & F University, China

Male genitalia generally exhibit species-specific morphology and have been widely used in taxonomy and phylogenetic analysis in many groups of insects. However, for the simpler and less varied female genitalia in most insects, the significance has been considerably overlooked or neglected in the phylogenetic analysis. Panorpidae are the largest family in Mecoptera, comprising ca. 420 species, and their phylogeny has been not investigated hitherto. Panorpa has been confirmed paraphyly for a long time. The diverse species of the Chinese Panorpa are categorized into four species groups [the P. amurensis, P. centralis (=P. cornigera), P. diceras and P. davidi groups]. The female genital plates of 26 species in four genera of Chinese Panorpidae were investigated using light and scanning electronic microscopy. The phylogenetic relationship was analyzed based on the female genital plates as well as other characters with Brachypanorpa carolinensis and Panorpodes kuandianensis as outgroups. The result shows that the female genital plate could provide reliable phylogenetic information for Panorpidae, especially valuable at generic level. In the cladogram, Sinopanorpa is evidently monophyletic. Neopanorpa is paraphyletic with Leptopanorpa. Panorpa is paraphyletic with both (Neopanorpa + Leptopanorpa) and Sinopanorpa. The P. amurensis, P. centralis, and P. diceras groups are evidently monophyletic and might display a potential generic status, respectively. The P. davidi group is very likely to be paraphyletic and need to further study. The origin and evolutionary pathway of the female genital plate in Panorpidae is briefly discussed.

Characteristics of genome sequence of "*Candidatus Hamiltonella defensa*", an endosymbiont of the whitefly, *Bemisia tabaci*

Qiong Rao[1], Shu-Sheng Liu[2], Xiao-Wei Wang[3]

[1]Zhejiang University, China, China, [2]Zhejiang University, China, [3]Zhejiang University, China, China

"Candidatus Hamiltonella defensa" is a maternally transmitted endosymbiont found sporadically in some sap-feeding insects. In some aphid individuals, the facultative symbiont Hamiltonella provides protection against parasitoid wasps by causing high mortality of wasp larvae, or induces the expression of host heat shock genes to increase host heat tolerance. In whitefly Bemisia tabaci complex, Hamiltonella is found in two important invasive cryptic species, MED and MEAM1. Herein, we report the properties of the draft genome sequence of Hamiltonella from an invasive whitefly, the MED cryptic species. The adequate bacterial DNA was obtained by whole genome amplification and then was sequenced using the Illumina HiSeq 2000. The paired-end reads were de novo assembled with SOAPdenovo v1.05. The coding sequences were predicted by Glimmer v3.0, and homologous comparison to a nonredundant public database was performed by BLAST for functional annotation. Finally, we obtained the draft genome of Hamiltonella, which has approximately 1.84 Mbp size with low GC content (40.3%) and comprises 404 contigs. Totally, 1,806 genes are predicted within the genome of Hamiltonella. Out of these genes, 1,112 were mapped to the pathways in KEGG, from which 'Membrane Transport' (n=301) has the highest percentage of genes followed by 'Replication and Repair' (n=227), 'Translation' (n=136), 'Carbohydrate Metabolism' (n=128), 'Metabolism of Cofactors and Vitamins' (n=88) and 'Amino Acid Metabolism' (n=87). These annotations provide a valuable resource for investigation of the functions of Hamiltonella in whitefly. Further genomic analyses and comparative studies will give additional insights into this symbiosis-host system.

Comparative analysis of mitochondrial genomes in Diplura (Arthropoda: Hexapoda) and its utility in Diplura phylogeny inference

Wan-Jun Chen[1], Yun-Xia Luan[2]

[1]*Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China,* [2]*Institute of Plant Physiology and Ecology, China*

Diplura is one of the most important groups of basal hexapods. There are three major lineages in Diplura: Campodoidea, Projapygoidea and Japygoidea. The monophyly of Diplura has been debated because Campodeoidea and Japygoidea differ in the type of cerci and ovarian structure. Some phylogenetic analysis based on molecular markers also do not support Diplura is a monophyletic clade. However, few studies have included Projapygoidea, whose phylogenetic position within Diplura is still a puzzle. Up to the present, there has been a noticeable lack of mitochondrial genome data from Projapygoidea. In this study, we determined and annotated the complete mitochondrial genome of Octostigma sinensis (Projapygoidea: Diplura), as well as three other new Diplura mitochondria genomes, one from Campodoidea and two from Japygoidea. All four newly sequenced together with three reported mitochondrial genome of diplura encode 13 protein-coding genes, 22 transfer RNAs and two ribosome RNA genes, and bear the same gene order as the pattern shared by most crustaceans and hexapods. Structural changes have occurred in trnR, trnC, trnS1 and trnS2 as previously reported, and reduction of tRNA arms were taxonomically correlated. The phylogenetic analysis based on 12 mitochondrial protein-coding genes (without nad4L) suggested that Diplura was a good monophyletic group and Projapygoidea was more closely related to Campodoidea than Japygoidea. We also noticed that in the phylogenetic analysis based on nucleotide information of protein-coding genes, the monophyly of Diplura cannot be recovered when Octostigma sinensis were excluded. This suggested that the lack of key taxon might get a wrong conclusion.

Systematics of the Australian triozid fauna (Hemiptera: Psylloidea) from the Casuarinaceae

Gary Taylor[1], Andy Austin[2], John Jennings[3], Matthew Purcell[4]

[1]University of Adelaide, Australia, [2]University of Adelaide, Australia, [3]University of Adelaide, Australia, [4]CSIRO Ecosystem Sciences, Brisbane, Australia

The triozid fauna of the Casuarinaceae is being used as a model system to determine whether insect herbivores and their hosts have co-speciated, providing a molecular basis for the selection of suitable biological control agents. It is hypothesised that phylogenies synchronous between herbivore and host would indicate a close evolutionary association, and therefore high host specificity and safer biological control options than a group that may have radiated on multiple host taxa. The phytophagous jumping plant-lice, or 'psyllids', appear highly host-specific, making them excellent candidates for co-phylogenetic studies. Most species are monophagous, few are oligophagous, and rarely polyphagous. Closely-related psyllids occur on closely related hosts, mostly recorded from single plant families. The triozid 'psyllid' fauna on Casuarinaceae is being revised: Aacanthocnema (6 spp.), Acanthocasuarina (6 spp), Trioza (4 spp.) and an undescribed genus (16 spp.) occurs on Allocasuaraina, and Casuarinicola (5 spp.), together with an additional undescribed genus (5 spp.) on Casuarina. Mapping of host data indicate two independent host switching events from Allocasuarina to Casuarina in the radiation of the Australian triozid fauna, and one of the gall-forming Schedotrioza to Eucalyptus. There is both a high generic-level and species-level host specificity between the triozids and their hosts suggesting their potential as biological control agents for species of Casuarina that are considered serious environmental weeds.

Phylogeny of Stylops (Strepsiptera) reveals the way of speciation through host specialization to host *Andrena* bees

Jakub Straka[1], Katerina Juzova[2]

[1]*Charles University in Prague, Czech Republic,* [2]*Charles University in Prague, Czech Republic*

Genus Stylops is a member of enigmatic insect order Strepsiptera. Their taxonomy or even ecology and other details about their biology are poorly known. Males are known for their extraordinary short life (just about five hours) and females are neotenic and all their life bound to the host body. We prepared DNA sequences for Stylops females from wide range of host species from Africa, Asia, Europe as well as North America. Based on these sequences, we constructed a phylogenetic tree to test the hypotheses of Stylops speciation. According to published literature, there are three different concepts: 1) every species of host Andrena possess its own specialized Stylops parasite; 2) every subgenus of host Andrena has its own particularly specialized Stylops parasite; 3) there is a single generalistic Stylops parasite. We discovered a wide range of biological variability, which probably came from coevolutionary history of every lineage of Stylops and its host Andrena species. Just the third hypothesis can be definitely rejected. We also provide several different views of possible mechanisms of speciation in this wonderful parasite species.

Preliminary phylogeny of early lineages of scale insects (Hemiptera: Coccoidea) based on adult male morphology from the early Cretaceous to recent

Isabelle Mifom Vea[1], David Alan Grimaldi[2]

[1]Richard Gilder Graduate School, American Museum of Natural History, U.S.A., [2]American Museum of Natural History, U.S.A.

Scale insects have profound significance in agriculture, forestry, and horticulture, which has necessitated a sophisticated species-level taxonomy. Phylogenetic work, however, lags behind taxonomy, particularly with regard to families that have traditionally been grouped into the probably paraphyletic "archeococcoids." This has also compromised the interpretation of the very diverse palaeofaunas of the Coccoidea, such as those beautifully preserved in amber from the Neogene to the Early Cretaceous (ca. 20-130 myo). Indeed, most fossil coccoids are winged males, but the taxonomy of Recent scales is based largely on the wingless, highly reduced females, further compromising fossil interpretation. Fortunately, the study of Recent adult males has increased greatly, thus allowing them to be incorporated into phylogenetic research. We report here the phylogenetic results of our work using males of exemplar Coccoidea through the past 130 million years to the present. A comparison is made of the chronology of coccoid divergence times with major events in earth history, such as the radiation of the angiosperms.

Cladistic analysis of Caelifera based on continuous-discrete morphological data

Maryam Yasemi[1], Mohsen Mofidi-Neyestanak[2], Alimorad Sarafrazi[3]

[1]student, Iran, [2]Researcher, Iran, [3]Reasercher, Iran

The phylogenetic relationships among some taxa within the suborder Caelifera (Orthoptera) were unclearly until now. In this study, 17 genus and species belonging to four superfamilies, three families, eleven subfamilies and two tribes were used as sample taxa and their phylogeny was studied using 56 discrete and 41 continuous morphological characters combined by simultaneous method. Also the mantid Iris oratoria (Mantidae: Dictyoptera) was selected as outgroup and Parsimony analyses were conducted via TNT Ver. 1.1 without weighting of any of the characters. The robustness of the clades was examined via bootstrapping test (1000 rep and 50% Del). The single most parsimonious (shortest-length) tree obtained was supported monophyly of Acridini and Truxalini tribes and also Tridactyloidea and Tetrigoidea superfamilies with 100 robustness. Also the results shows that the subfamilies Teratodinae, Calliptaminae and Eyprepocnemidinae that are traditionally classified within the Acrididae are grouped together in a clade that is named here as Teratodidae. Moreover, based on Dericorythidae and Cyrtacanthacridinae as sister group with high robustness is proposed to consider the Dericorythidae as subfamily Dericorythinae. In this evolutionary tree 2 subfamilies Pamphaginae and Tropidaucheninae are supported as a sister group with 97 robustness.

CalBug: Digitizing California terrestrial arthropod collections

Peter T. Oboyski[1], Joan E. Ball[2], Kipling Will[3], Rosemary G. Gillespie[4]

[1]University of California, U.S.A., [2]University of California, U.S.A., [3]University of California, U.S.A., [4]University of California, U.S.A.

Natural history collections house over a billion insect specimens worldwide collected over several centuries. Specimen labels encode data denoting species, location, and date captured used to study biogeographic patterns, spread of invasive species, and responses to environmental change. However, access to data is impractical for most of the research community. Because of enormous collection sizes, entomology has lagged behind other disciplines in digitizing collections. In 2010, the Essig Museum began a collaborative five-year project among eight California museums with a goal to digitize and geographically reference over one million specimens from target groups and localities. A major goal is streamlining data capture while maintaining data integrity and specimen safety. Digital imaging of labels reduces the need for repeated handling of specimens, allows enlargement of difficult to read text, and enables outsourcing of data transcription. Transcription is aided by a web-based citizen science program through collaboration with the Citizen Science Alliance. Data from each label are keyed by multiple volunteers and compared for consistency. Data are vetted in-house, normalized for variations in locality descriptions, then repatriated to an online, open-access MySQL data cache. Georeferencing of localities will occur later using semi-automated services, such as BioGeomancer, following standard protocols. The greatest bottleneck in digitizing collections is the handling of individual specimens and labels. Using high-efficiency workstations labels are removed from pins, digitally imaged with unique identifiers, repinned, and returned to their trays. Annotation of images and naming of files are done with batch processing software. Other innovations and progress-to-date will be discussed.

Orthoptera of the Pan-Japan sea area: Taxonomic diversity, distribution and origin

Sergey Yurievich Storozhenko
Russian Academy of Sciences, Vladivostok, Russia

The region around the Sea of Japan include the basin of Amur River in China (provinces Heilongjiang and Jilin) and Russian Far East, Korean Peninsula, Sakhalin Island, South Kuril Islands and main islands of Japan (without Ryukyu). Totally 441 species (or 470 nominal taxa including species and subspecies) from 149 genera in 33 subfamilies and 16 families of Orthoptera are recorded from this area. Beside them 249 species in 114 genera are known from mainland and 310 species in 122 genera recorded from islands. The fauna of Orthoptera of the Pan-Japan Sea area generally is characterized by dominance of endemic to this region species, the sum of which is 65 % of the whole fauna. East-Palaearctic (18 %) and Oriental-Palaearctic species (10 %) are also common, but the sum of Afro-Eurasian, Australian-Palaearctic and Holarctic species is only 7 %. The patterns of distribution and diversity of the Orthoptera that we see today are closely associated with the history of the Sea of Japan since the Miocene. But the modern fauna of Orthoptera were basically formed during the course of the Late Wurm regresses and subsequent Holocene transgressions. The sea level in the Late Wurm climatic minimum fell some 130 meters, resulting in land bridges between Asian mainland and islands. At the end of the Wurm, the climate warmed once again, resulting in a rise of sea level. During the Holocene climatic optimum, there was a rather good chance for migration of thermophilic species of Orthoptera to the north.

Cryptic termite species diversity in Kakamega Forest, Kenya

Zipporah Bisieri Osiemo[1], Andreas Marten[2], Godfrey H. Kagezi[3], Johanna P.E.C. Darlington[4], Manfred Kaib[5], Linus M. Gitonga[6], Hamadi I. Boga[7], Roland Brandl[8]

[1]University of Marburg and Jomo Kenyatta University of Agriculture and Technology, Germany and Kenya, [2]University of Marburg, Marburg , Germany, [3]Kawanda Agricultural Research Institute, Uganda, [4]University of Cambridge, United Kingdom, [5]University of Bayreuth , Germany, [6]Jomo Kenyatta University of Agriculture & Technology, Kenya, [7]Jomo Kenyatta University of Agriculture & Technology , Kenya., [8]University of Marburg, Marburg , Germany

Termite workers are morphologically rather uniform, and thus exhibit only few traditional taxonomic characters for species identification and yet they dominate in ecological surveys. Therefore, the diversity of termites is poorly understood, especially in tropical forests which are hotspots of biodiversity and threatened by disturbances. Recently, the use of DNA- barcoding has become more important for inventory and biodiversity assessment of hyperdiverse taxa and those which are difficult to identify. An approach towards establishing a DNA barcode library for termite species identification and biodiversity assessment using sequences of the mitochondrial COII gene is presented in this study. Kakamega forest is the remnant of the Congo-Guinean Forest reaching Kenya. This isolated forest is a hotspot of biodiversity which is threatened by the increasing human population. Hence, to interpret the role of termites in different land-use habitats, the species composition needs to be understood. Here we present termite biodiversity assessment using sequences of the mtCOII gene. At least 16 termite species were observed in Kakamega Forest by morphological determination whereas at least 22 species (MOTUs) were found by molecular species delimitation.All species assessed were belonging to the family Termitidae (higher termites), and among them the fungus-growing Macrotermitinae were most prevalent with at least eight putative species, which were all cryptic within their three different genera (Microtermes, Pseudacanthotermes and Odontotermes). This highlights the advantage that molecular based species delimitation and reveals some morphological cryptic species.

Immune inducible factors in the cuticle of the silkworm, *Bombyx mori*

Tsunaki Asano
Tokyo Metropilitan University, Japan

Insect cuticle is a non-cellular matrix composed of proteins, carbohydrates and chitins. The cuticle is often regarded as just a "physical armor". However, it contains water, which enables biochemical reactions to occur, and various types of defense systems, such as anti-microbial peptides and melanization cascade, are found in the cuticle matrix. To find novel factors involved in defense reaction in insect cuticle, proteomic analyses were performed using larvae of the silkworm, Bombyx mori. Suspension of Gram-positive bacteria was injected into the hemocoel of the fifth instar larvae, and after 24 hours cuticle proteins were extracted with acidified buffer. The proteins were subjected to 2D-PAGE, and the pattern of electrophoresis was compared with that of the control larvae. Proteins, the amounts of which were increased after bacterial injection, includes antibacterial peptides, components of prophenoloxidas cascade and other molecules that have already been mentioned about their possible involvements in defense reactions in the hemolymph. Some proteins, which are candidates of novel immune inducible factors, are assumed to exhibit epithelial expressions, considering the expression patterns of the Drosohpila orthologs. The Drosophila mutants of these possible "cuticle specific" factors exhibit excess melanization reactions that might be caused by abnormal regulation of melanization cascade or increased infection. The weakened cuticle structures leading higher probability of wound can be also the reasons of the excess melanization. The relationship between the molecular functions of the factors and their possible involvements in defense reaction in the cuticle is discussed.

The characterization of a concentration-sensitive α-adrenergic-like octopamine receptor found on insect immune cells and its possible role in mediating stress hormone effects on immune function

Shunfan Wu[1], Jia Huang[2], Gongyin Ye[3]

[1]Zhejiang university, China, [2]Zhejiang university, China, [3]Institute of insect sciences, China

Octopamine (OA), the insect equivalent of norepinephrine, links the nervous system and immune system in insects. This study examines the underlying molecular mechanisms (i.e. second messenger systems) mediating OA effects on insect immune cells. At low concentrations (< 1 μM), OA stimulated hemocyte spreading and phagocytosis in the larval Lepidopteran (caterpillar) Chilo suppressalis, whereas at high concentrations (> 10 μM), OA inhibited hemocyte spreading and phagocytosis. Similarly, OA concentration had differential effects on two intracellular signaling pathways, Ca2+ and cAMP. Low concentrations of OA increased intracellular Ca2+, but only high concentrations of OA (>1 μM) led to an increase in both Ca2+ and cAMP. We identified an α-adrenergic-like octopamine receptor in this species (CsOA1) and confirmed that it is expressed in hemocytes. After heterologous expression in HEK-293 cells, the CsOA1 receptor produced the same OA concentration-dependent responses on intracellular Ca2+ and cAMP as had been observed in hemocytes. These findings support earlier work showing that OA has both stimulatory and suppressive effects on immune responses, depending on the OA concentration. Our evidence suggests that these biphasic effects are mediated by an octopamine receptor signaling through intracellular Ca2+ and cAMP second messenger pathways. Stress hormones/neuromodulators have complex effects on immune function in animals across phyla. This complexity may be mediated, in part, by conserved connections between adrenergic-like G-coupled protein receptors and second messenger systems.

Hemomucin, an O-glycosylated protein on embryos of wasp *Macrocentrus cingulum* protect them from being encapsulated by hemocytes of host *Ostrinia furnacalis*

Jian Hu[1], Shengfeng Hu[2], Qiuyun Xu[3], Wenqing Zhang[4]

[1]Sun Yat-sen University, China, [2]Sun Yat-sen University, China, [3]Sun Yat-sen University, China, [4]Sun Yat-sen University, China

Hemomucin, an O-glycosylated protein on embryos of wasp Macrocentrus cingulum protect them from being encapsulated by hemocytes of host Ostrinia furnacalis Jian Hu, Shengfeng Hu, Qiuyun Xu, Wenqing Zhang State Key Laboratory of Biocontrol, Sun Yat-sen University, Guangzhou 510275, China Abstract Dozens of embryos of M. cingulum, a polyembryonic parasitoid may grow and develop in host's hemocoel, but how they avoid the immune reaction from host hemocytes is still unclear. In this study, hemomucin in M. cingulum (McHem) was proven to protect wasp from being encapsulated by host hemocytes. McHem is a transmembrane protein with a typical mucin domain containing 51 O-glycosylation sites and specifically conjugated with Helix pomatia lectin. Q-PCR and western blotting results indicated that McHem expressed highly in eggs, morulae and secondary embryos, but less in larvae and adult. Immunohistochemistry analysis showed that McHem mainly located on the surface of extra embryonic membrane. When the secondary embryos were transplanted into unparasitized host larvae, they proliferated into dozen of embryos, however, after the wasp's embryos were incubated with the anti-McHem serum in vitro and then were transplanted, they will not proliferated and more than 90% of them were encapsulated by host hemocytes ($p<0.01$). Furthermore, cultured with dsRNA of McHem added Ex-cell 420 medium in vitro and then transplanted, much more wasp embryos were encapsulated by host hemcoytes compare to the embryos cultured in dsGFP added medium ($p<0.01$). All these results indicated that hemomucin should play an important role in M. cingulum avoiding host's cellular immune reaction.

Cytolytic activity in the mosquito, *Armigeres subalbatus*

Toshinori Sasaki[1], Mutsuo Kobayashi[2]

[1]*National Institute of Infectious Diseases, Japan,* [2]*National Institute of Infectious Diseases, Japan*

Although cytolysis of invading organisms is an innate form of immunity used by invertebrates, so far the underlying mechanism remains less explored. The pupal hemolymph of the mosquito Armigeres subalbatus induces an activity that causes hemolysis of human red blood cells (HRBC). This hemolytic activity was inhibited by sialic acid (N-acetylneuraminic acid) and serine protease inhibitors. We purified the sialic acid-specific lectin(s) from the pupal hemolymph using formaldehyde-fixed HRBC and determined the sequence of the amino-terminal 19 amino acid residues. A polyclonal antibody produced against this N-terminal peptide clearly inhibited the hemolytic activity of the hemolymph in vitro, thus suggesting that the hemolysis of HRBC is caused by the lectin present in the mosquito hemolymph. We suggest that mosquitoes possess a cytolysis system.

Venomic studies of an endoparasitoid *Pteromalus puparum*

Gongyin Ye[1], Qi Fang[2], Lei Wang[3], Yu Zhu[4], Zhichao Yan[5], Fei Wang[6], Cui Hu[7]

[1]Zhejiang University, China, [2]Zhejiang University, China, [3]Zhejiang University, China, [4]Zhejiang University, China, [5]Zhejiang University, China, [6]Zhejiang University, China, [7]Zhejiang University, China

The relationships between parasitoids and their insect hosts have attracted much attention. Females of the gregarious endoparasitoid Pteromalus puparum (Hymenoptera: Pteromalidae) inject only venom along with eggs into their hosts. Here we report the venomic results of P. puparum. To facilitate research on P. puparum, we presented a method for de novo assembly of the transcriptomes of venom gland and the rest of wasp body, respectively, using short read sequencing technology (Illumina). In parallel, proteins from pure venom were separated and individually identified by LC-MS/MS analysis or reversed phase HPLC combined with N-terminal sequencing methods, compared with transcriptomic data and the non- redundant from public database. About 60% of identified venom proteins were specifically expressed in venom gland and secreted into the venom reservoir, according to the results of comparatively transcriptomic analysis between venom gland and the rest of wasp body. A set of potentially bioactive components identified from this parasitoid venom were recombinantly expressed and then the immunosuppressively functional studies of the recombinant proteins on the pupal host P. rapae were performed. Our findings support our hypothesis that P. puparum venom is a complex substance with a large number of components regulating host immune responses. We conclude that the actions of venom on host biology in ways that benefit the development and emergence of the next generation of parasitoids.

The Diadegma fenestrale was known as parasitoid on potato tuber moth, Phthorimaea operculella and diamondback moth, Plutella xylostella. This species, genus Diadegma are first reported from Korea. Diadegma fenestrale polydnavirus; ichnovirus (DfIV) observed in D. fenestrale calyx. DfIV showed typical ichnovirus shape which two membranes surround virus capsids. The genome contents of DfIV consist about twenty-three double-stranded DNA segments ranging 1.8 to 12 kb. Total DfIV genome size was estimated to be about 115kb by adding all segment size. To identify DfIV genes, whole genome sequencing based on GS-FLX was conducted using purified total DNA extracted from D. fenestrale calyx. About sixty ORFs were analyzed and several typical polydnavirus gene family detected such as cys-motif, rep, vinnexin and vankyrin. This is the first report of DfIV and these lepidopteran host immune suppression genes and ecological characteristics will be deeply identified.

Pattern recognition receptors acting in innate immune system of shrimp against pathogen infections

Jin-Xing Wang
Shandong University, China

Invertebrates only have innate immunity, and pattern recognition is their main strategy for pathogen discrimination. Much work has been performed on the innate immunity of the shrimp, especially on immune recognition, due to its great economic value. These studies revealed the recognition mechanism of shrimp at a certain degree. To date, 10 types of pattern recognition receptors (PRRs) have been identified in shrimp, namely, beta-1, 3-glucanase-related proteins, beta-1, 3-glucan-binding proteins, C-type lectins, scavenger receptors, galectins, fibrinogen-related proteins, thioester-containing protein, Down syndrome cell adhesion molecule, serine protease homologs, and trans-activation response RNA-binding protein (TRBP). A number of PRRs have been functionally studied and have been found to have diffident binding specificities and immune functions. This work was supported by the National Natural Science Foundation of China (Nos. 31130056, 30770282) and the Ph.D. Programs Foundation of the Ministry of Education of China (No. 20110131130003).

A novel polydnaviral gene family, BEN, and its immunosuppressive function in larvae of *Plutella xylostella* parasitized by *Cotesia plutellae*

Md. Ramjan Ali[1], Yonggyun Kim[2]

[1]*Andong National University, Republic of Korea,* [2]*Andong National University, Republic of Korea*

A full genome sequence of the episomal form of Cotesia plutellae bracovirus (CpBV) suggests eleven BEN family genes. This study analyzed their expression and physiological function in the viral host, Plutella xylostella. All eleven BEN family genes were expressed during entire parasitization period of P. xylostella larvae. In addition, these BEN family genes were expressed in fat body, gut, epidermis, and hemocytes in final larval instar of parasitized P. xylostella. The eleven BEN family genes were transiently expressed in nonparasitized larvae by injection of each viral segment containing its corresponding BEN family gene. The transient expression of BEN family genes significantly suppressed hemocyte nodule formation in response to bacterial challenge. Subsequent injection of double-stranded RNA specific to each BEN family gene suppressed the expression of the BEN family gene and rescued the immunosuppression. We propose BEN domain-containing genes as a new functional gene family in polydnaviruses. To determine a molecular interaction of BEN proteins, a BEN gene (CpBV-ORF3302) was expressed in Escherichia coli and purified. Pull-down experiments using recombinant BEN protein against cytoplasmic and nuclear extracts of P. xylostella larvae suggest that BEN may interact signal transduction and chromatin remodeling to alter host gene expression.

A viral histone H4 interacts with nucleosome components and alters target insect transcriptome revealed by an Illumina RNASeq

Rahul Pralhad Hepat[1], Yonggyun Kim[2]

[1]*Andong National University, Republic of Korea,* [2]*Andong National University, Republic of Korea*

A viral histone H4 is encoded in a polydnavirus called Cotesia plutellae bracovirus (CpBV), which is symbiotic to an endoparasitoid wasp, C. plutellae. Compared to general histone H4, the viral H4 possesses an extra N-terminal tail containing 38 amino acid residues, which has been presumed to control host gene expression in an epigenetic mode. This study addressed its molecular interaction with host nucleosomes and its target genes to be altered in their transcription by an Illumina RNASeq. Reassociation of nucleosome components with a recombinant CpBV-H4 produced octamers containing each monomer of H4 and CpBV-H4 plus dimers of H2A, H2B, and H3, which were separated by a size-exclusion chromatography and analyzed by SDS-PAGE. Transient expression of CpBV-H4 in a model insect, Tribolium castaneum, was performed by microinjection of a recombinant expression vector and confirmed by RT-PCR and immunoblotting. Under this transient expression condition, total RNAs were extracted and read with an Illumina HiSeq 2000. Annotated transcripts were classified into different GO categories and compared with those of control insects injected with a non recombinant expression vector. Genes showing significant differences (P < 10-5) in corrected transcript levels were determined to be targets manipulated by expression of CpBV-H4. When the target genes were physically mapped, they were scattered on entire chromosomes of T. castaneum. Moreover, the target genes were not significantly different with a typical transcriptome at the developmental stage. These suggest that the viral histone H4 alters host gene expression by a direct molecular interaction with target insect nucleosomes without specificity.

Utilization of microRNA mimics and inhibitors in pest control

Balachandran Jayachandran[1], Mazhar Hussain[2], Sassan Asgari[3]

[1]University of Queensland, Australia, [2]University of Queensland, Australia, [3]University of Queensland, Australia

MicroRNAs (miRNAs) as ~21 nucleotide non-coding small RNAs have emerged as key factors in gene regulation involved in various biological processes. In this study, a larval-specific miRNA, har-miR-2002b, was identified from Helicoverpa armigera. For the first time, we explored the possibility of utilizing synthetic inhibitor and mimic of miRNA by oral feeding and confirmed that the inhibitor and mimic can successfully inhibit/oversupply the miRNA in H. armigera larvae. Bioassays by oral feeding indicated 70% reduction in fecundity and 40% larval mortality in the presence of har-miR-2002b mimic. In addition, a large proportion of those larvae that made it to the pupal stage were deformed and only few moths emerged from them. This implied an important role of har-miR-2002b in larval development and adult fecundity. A trypsin-like serine protease (Ha-TLP) was identified as a target of har-miR-2002b. In vivo and in vitro studies revealed that in the presence of the miRNA mimic Ha-TLP transcript levels were significantly down-regulated. In contrast, inhibition of har-miR-2002b led to significant up-regulation of Ha-TLP transcript levels. This is the first study which shows the potential of utilization of miRNA mimics and inhibitors in pest control by targeting specific insect genes.

Pigment synthesis pathway genes and their application to visible transgenic markers

Mizuko Futahashi[1], Ken-Ichiro Tatematsu[2], Kimiko Yamamoto[3], Keiro Uchino[4], Ryo Futahashi[5], Toshiki Tamura[6], Hideki Sezutsu[7]

[1]National Institute of Agrobiological Sciences, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]National Institute of Agrobiological Sciences, Japan, [4]National Institute of Agrobiological Sciences, Japan, [5]National Institute of Advanced Industrial Science and Technology (AIST), Japan, [6]National Institute of Agrobiological Sciences, Japan, [7]National Institute of Agrobiological Sciences, Japan

Ommochromes and melanins are major pigments involved in reddish and blackish coloration in insects. However, molecular mechanisms of the synthesis of these pigments are not fully understood. Here we report our recent findings on pigmentation mutants of silkworm Bombyx mori and their application to visible molecular markers. For the first topic, we will talk about the identification of the gene responsible for the egg and eye color mutant, red egg (re) by positional cloning, mutant analysis, and RNAi experiments. The eggs of re mutant display a pale orange color instead of normal dark coloration, and have been suggested to have a defect in the biosynthesis of the final ommochrome pigments. The gene responsible for the re mutant was a novel major facilitator superfamily transporter. Interestingly, the re gene homolog were found in all insect genomes sequenced at present, except for twelve sequenced Drosophila genomes, which seemed to correlate with the previous studies that have demonstrated that eye ommochrome composition is different from other insects in several Dipterans. For the second topic, we will report the development of a dominant visible marker for insect transgenesis using a gene responsible for a silkworm melanin synthesis mutant. This marker changed the color of newly hatched first-instar silkworm larvae from black to a distinctive light brown color. Suppression of black pigmentation could be observed throughout the larval stages and adult. The widespread distribution of melanin pigments suggests its potential to be applied to diverse insect taxa.

Transcriptome analysis of the oriental fruit fly *Bactrocera dorsalis* (Diptera: Tephritidae)

Weiwei Zheng[1], Tao Peng[2], Hongyu Zhang[3]

[1]College of Plant Science and Technology, Huazhong Agricutural University, China, [2]College of Plant Science and Technology, Huazhong Agricutural University, China, [3]College of Plant Science and Technology, Huazhong Agricutural University, China

Bactrocera dorsalis is a widely spread polyphagous pest feeding on more than 250 fruits and vegetables. Currently, there is no ideal control program. To identify more molecular targets involved in reproduction and development in B. dorsalis and finally effective control on these pests, the transcriptome for the B. dorsalis from the whole body at different developmental stages was produced using 454 pyrosequencing. In a single run, 747,206 sequencing reads were obtained and assembled into 28,782 contigs and 169,966 singletons. Additionally, we identified a great number of genes involved in reproduction and development as well as genes that represented nearly all major conserved metazoan signal transduction pathways, such as insulin signal transduction. Furthermore, transcriptome changes during development were analyzed. A total of 2,977 differentially expressed genes (DEGs) were detected between larvae and pupae libraries, while there were 1,621 DEGs between adults and larvae, and 2,002 between adults and pupae. These DEGs were functionally annotated with KEGG pathway annotation and 9 of them were validated by qRT-PCR. Our data provide for the first time access to the genetic architecture of reproduction and development as well as major signal transduction pathways in the Tephritid fruit fly pests, allowing us to elucidate the molecular mechanisms underlying courtship, ovipositing, development and detailed analyses of the signal transduction pathways.

Characterize the functions of candidate effectors in aphid by RNA interference

Shan-Shan Guo[1], Meng Zhang[2], Tong-Xian Liu[3]

[1]Northwest A & F University, China, [2]Northwest A & F University, China, [3]Northwest A & F University, China

Aphids are among the most devastating insects of plants. As a phloem-feeding insect, aphid punctures sieve tubes with stylet and uptakes phloem sap to ingest nutrients. From the onset of stylet penetration, aphid secretes two types of saliva into plant tissues: gelling saliva that forms a sheath surrounding stylet, and watery saliva that contributes to further penetration and ingestion. Similar to the interaction between pathogen and plant during invasion, some proteins and other chemical constituents in aphid's saliva may act as effectors which trigger or suppress plant's immune system. We focused on secretory proteins expressed in aphid's saliva to select effectors which are essential in feeding process, especially in the course of interaction between aphids and plants. To screen genes in salivary glands playing important roles in aphid feeding processes, double-stranded RNA (dsRNA) was delivered to aphids through artificial feeding. Considering Arabidopsis thaliana a model plant and powerful genome resource, Myzus persicae and Acythosiphon pisum were selected. We found that feeding dsRNA to the two aphid species, target gene transcript levels in treatment group ranged from 20% to 50% compared to control group. We also observed that knockdown some of the candidate genes can affect nutrients ingestion.

Social interactions and gene expressions involved in the soldier differentiation of a termite *Reticulitermes speratus*

Dai Watanabe[1], Toru Miura[2], Kiyoto Maekawa[3]

[1]Hokkaido University, Japan, [2]Hokkaido University, Japan, [3]University of Toyama, Japan

The complex social organization of termite colonies requires sophisticated regulatory mechanisms to adjust caste composition to the colony needs. In this aspect, the presence of soldiers is known to regulate soldier differentiation. Soldiers originate from workers. Their differentiation, which can be induced by juvenile hormone (JH) application, is inhibited in presence of soldiers. In our previous study, the presence of soldiers was shown to decrease JH titer in workers treated with JH III. However, what factors mediate the soldier presence and how JH titer is controlled are currently unknown. Here, we investigate these mechanisms using the lower termite Reticulitermes speratus. Firstly, we investigated the frequency of trophallaxis and the duration of grooming between workers and soldiers in the dishes treated with JH III. These behaviors are thought to be candidates transferring the soldier effects. As a result, we found that when they are treated with JH III, workers spend longer time grooming soldiers. Therefore, soldier effects seem to be transferred during grooming behavior. Secondly, we investigated the gene expression in workers reared in presence and absence of soldiers. Based on the qPCR of various genes involved in the JH pathway, our results showed that the expression of cytochrome P450 genes, namely, RsCYP4C46 and RsCYP15A1 decreased in workers reared with soldiers. These genes are thought to contribute to the JH synthesis and secretion, suggesting that the worker corpora allata are suppressed by the soldier presence, that in turn causes the rapid decrease of JH titer in workers.

Keywords:*termite, soldier differentiation, caste regulation, grooming, corpora allata*

Bactrocera dorsalis shows RNAi to orally feeding dsRNAs and bacteria expressing dsRNAs

Xiaoxue Li[1], Mingyan Zhang[2], Hongyu Zhang[3]

[1]College of Plant Science and Technology, Huazhong Agricutural University, China, [2]College of Plant Science and Technology, Huazhong Agricutural University, China, [3]College of Plant Science and Technology, Huazhong Agricutural University, China

The oriental fruit fly, Bactrocera dorsalis, is a devastating agricultural pest in tropical and subtropical region, causing millions of loss to fruit crops such as citrus and guava. RNA interference is a powerful tool to inhibit target gene expression which makes this technology a useful method in IPM. Here we report that directly feeding dsRNA or engineered Escherichia coli strain HT115 expressing dsRNAs both caused RNAi effect in adult flies. Fragment of target genes were cloned into L4440. Then E.coli strain HT115 were transformed with recombinant vectors to express dsRNA in vitro. dsRNAs were designed targeting genes that encode ribosomal protein Rpl19, ATPase D, the fatty acid elongase Noa and GTPase Rab11. Adult flies were fed either by dsRNAs or engineered bacteria for continuous 7 days. Results show that both methods successfully cause RNAi in B.dorsalis. The maximum decrease of target gene expression vary from 35% to 100%. Tissue specific expression examination indicated that RNAi could be achieved in a tissue-specific way. Up-regulations of target genes were observed in the experiments using both methods. For example, in ds-rpl19 treated group, up-regulation occurred on day 2 and day 4 with each 3 times and 8 times compared to ds-egfp treated control group. This phenomenon could also be observed in ds-rab11 and all engineered bacterial treated group

The Pax6/eyeless gene and the development of Collembolan eyes

Yanan Hou[1], Yuxia Luan[2], Sheng Li[3]

[1]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [2]Institute of Plant Physiology and Ecology, Shanghai Institutes for Biological Sciences, China, [3]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China

Collembola is a group of small, entognathous, and wingless basal hexapods. Some Collembolan species have 1+1 to 8+8 ommatidia, but some have no eye. Therefore, it's very interesting to study their eye polymorphism. Pax6/eyeless gene had been widely proved to be related with eye development across the animal kingdom. As a transcription factor, it contains two conserved domains (the Paired domain, PD and the Homeodomain, HD), a variable linker region and a C-terminal transactivation domain. In this study, we choosed two Collembolan species, the eyeless Folsomia candida and the eyed Ceratophysella denticulata (8+8 eyes) for comparison. First, the Pax6/eyeless genes of two species were cloned and sequenced. Their amino acids sequence of PD and HD showed high conservation, but other regions were highly divergent. Then, the transgenic Drosophila melanogaster with Pax6 genes from both species were explored to study the function. The intact Pax6 of the eyed Collembolan species can induce ectopic compound eyes on the legs and wings of adult fruitfly, although the induced eyes with reduced shapes and reduced ommatidia numbers. However, the intact Pax6 of the eyeless species can't. When the Pax6 C-terminal of the eyeless species was replaced with the corresponding protein region of the eyed species, the chimeric gene can induce ectopic eyes. On the contrary, the chimeric gene of eyed Pax6 gene with the C-terminal of eyeless species can't induce ectopic eyes in Drosophila. The preliminary results suggested that the C-terminal of Pax6 gene is crucial for the Collembolan eye polymorphism.

Effects of plant growth promoting rhizobacteria (PGPR) on induction of plant volatiles and consequences for insect-plant interactions

Henry Fadamiro[1], Esther Ngumbi[2], Kate Nangle[3], Joseph Kloepper[4]

[1]Auburn University, U.S.A., [2]Auburn University, U.S.A., [3]Auburn University, U.S.A., [4]Auburn University, U.S.A.

Plant growth-promoting rhizobacteria (PGPR) represent a wide range of root-colonizing bacteria whose application is often associated with increased rates of plant growth, suppression of soil pathogens, and the induction of systemic resistance. The effects of application of PGPR on induction of volatile organic compounds (VOCs) in treated plants and consequences for insect-plant interactions have gone largely unexamined. Studies were conducted to test the hypothesis that PGPR alters cotton plant VOCs with possible consequences for plant-insect and tritrophic interactions. Three PGPR strains were tested. Strains were applied as spore preparations and headspace volatiles were collected from PGPR-treated and untreated cotton plants four weeks after planting. Results showed quantitative and qualitative differences in headspace volatiles of PGPR treated versus untreated plants. Host acceptance tests with beet armyworm, Spodoptera exigua (Lepidoptera: Noctuidae) showed that females prefer to lay eggs on untreated cotton compared to PGPR-treated cotton plants. Four choice olfactometer behavior experiments with Microplitis croceipes (a hymenopteran parasitoid of cotton bollworm) revealed that PGPR-treated plants were highly attractive to the parasitoids. These results demonstrate that PGPR alters production of VOCs in cotton, and that herbivores and parasitoids are capable of exploiting these differences in VOCs.

RNAi knockdown of DNA methylation affects gene splicing in the honey bee *Apis mellifera*

Hongmei Li
University of Illinois at Urbana Champaign, U.S.A.

Epigenetics is increasingly appreciated as a process to help explain how genomic sequences give rise to complex phenotypes. DNA methylation is known to regulate gene expression, but recent studies suggest it also may be involved in alternative splicing of transcripts. To investigate this phenomenon in honey bees, we developed a novel methodology for non-invasive high-throughput application of silencing RNAs in vivo in adult bees. Small interfering (si) RNA-nanoparticles complexes are administered to bees by nebulization and these complexes reach cells via the tracheal system. Using this method we treated bees with DNA methyl-transferase 3 (DNMT3) siRNAi and assessed results with RNAseq of abdominal tissue. Analysis of RNAseq data was performed via a novel computational program, TrueSight, that performs better than existing programs in providing quantitative measurements of alternative splicing. Analysis of control and DNMT3-RNAi transcriptomes revealed alternatively spliced isoforms for about 48% of the genes. DNMT3-RNAi caused statistically significant effects on 4 different types of splicing patterns: exon skipping, alternative start/terminal site, alternative 3'/5' site, and intron retention events. Gene Ontology analysis revealed that the set of genes showing DNMT3-RNAi caused differences in alternative splicing was enriched for phosphoprotein, nucleotide-binding, and ATP-binding genes. These results indicate that DNA methylation in honey bees plays a strong role in regulating alternative splicing of transcripts. Future studies will focus on the role of epigenetics in regulating honey bee phenotypic plasticity.

Comparative fat body transcriptome analysis of sunn pest in overwintering and summer populations

Nurper Guz[1], Umut Toprak[2], Dwayne Hegedus[3], Cathy Coutu[4], Asli Dageri[5], Mouzgan Mousavi[6], Serife Bayram[7], Oktay Mehmet Gurkan[8]

[1]Ankara University, Turkey, [2]Ankara University, Turkey, [3]Agriculture and Agri-Food Canada, Canada, [4]Agriculture and Agri-Food Canada, Canada, [5]Ankara University, Turkey, [6]Ankara University, Turkey, [7]Ankara University, Turkey, [8]Ankara University, Turkey

Sunn pest is the main pest of wheat and barley in wide areas of Turkey and the Middle East. It overwinters at altitudes, usually under bushes of Artemisia, Kochia, Acantholimon. Its hibernation is a physiological requirement in terms of its survival. The most important modification between overwintering and feeding individuals is the difference in lipid metabolism. In most insects, stored lipid reserves are used during diapause in order to supply the energy demand. Fat body is rich in mRNA and it serves as an expression site of most genes. Roche 454 pyrosequencing has become a method of choice for generating transcriptome data from non-model organisms. In this study, we have generated two different cDNA libraries from the fat bodies of feeding adults in summer and dormant adults in winter in order to characterize the genes controlling lipid storage mechanism which is a necessity in sunn pest's biological cycle. We obtained more than 200.000 high quality sequencing reads from a 454 GS FLX Titanium pyrosequencer (mean length: approximately 400 base pairs). We analyzed the putative fat body transcriptome based on homology to other gene products with known functions available in the public domain. We found genes that showed differential overall expression by comparison of two transcriptomes. Our sequencing and annotation framework will provide a simple and effective way to achieve high-throughput gene discovery for organisms lacking a sequenced genome. Furthermore the database revealed from this study will also provide a valuable resource for developing specific pest management strategies.

Is older stronger? Correlates of ester metabolism with task-related polyethism in *Apis mellifera*

Ling-Hsiu Liao[1], May R. Berenbaum[2], Joel R. Coats[3]

[1]University of Illinois at Urbana-Champaign, U.S.A., [2]University of Illinois at Urbana-Champaign, U.S.A., [3]Entomology, Iowa State University, Ames, IA, U.S.A.

Esterases have been considered among the main detoxification enzyme groups in insects. Due to task allocation in honey bee social development, we hypothesized that polyethism would be accompanied by variation in enzyme activities in individuals according to caste and task. The metabolism of seven ester compounds in honey bees was assayed in vitro. Our study shows that the midguts from workers in different stages (newly emerged worker, nurse bee and pollen forager) and from drones are all capable of detoxifying aliphatic esters [octyl butyrate(OB), octyl acetate(OA), hexyl butyrate(HB) and butyl butyrate(BB)] and monoterpenes [myrtenyl acetate(MA), thymyl acetate (TA) and perillyl acetate(PA)]. However, nurse bees and pollen foragers have higher esterase-mediated metabolic rates than newly emerged workers and drones for OA, HB, BB and MA. Because nurse bees are responsible for feeding the grubs, their elevated rates of ester metabolism may be related to the requirement of processing the raw food, such as pollen, which is not possessed by newly emerged workers and drones. Also, the esterase system may need time to develop in newly emerged workers. Moreover, older bees usually produced a lower amount of 1-octanol, a product of OA or OB metabolism, but they consume substrates at higher rates than younger bees. Since 1-octanol is one of the components of the honey bee alarm pheromone, young bees, which would be unlikely to participate in a major way in colony defense, may not have the capacity to metabolize alarm pheromone.

Research progress of target and detoxification enzymes related to resistance of *Bactrocera dorsalis*

Guangmao Shen[1], Guangmao Shen[2], Wei Dou[3], Jinjun Wang[4]

[1]Southwest University, China, [2]Southwest University, China, [3]Southwest University, China, [4]Southwest University, China

The oriental fruit fly, Bactrocera dorsalis, is a major pest causing severe damage to agriculture worldwide, and developed insecticides resistance rapidly. We have conducted the transcriptome analysis of B. dorsalis, obteined a huge number of gene sequences encoding insecticide targets and detoxification enzymes. Based on the data, a series experiments were carried out to investigate specific gene functions related to resistance. Biochemical and molecular characteristic analysis of purified AChE from four field populations and different developmental stages proved that decrease of susceptibility of B. dorsalis was mainly caused by the decrease of AChE activity. It was in accordance with previous study that the alterations of AChE were correlated with resistance to organophosphate insecticide. The full cDNA sequences of other important target genes were sequenced including a VGSC gene (6446 bp), and four nAChR genes. PCR-RFLP was used to identify whether point mutations related to resistance existed. Eighteen full sequences of GST genes were isolated. Their expression profile among developmental stages, different tissues, and insecticides induced strains were detected. The results suggested that GSTs were involved in detoxification of abamectin and beta-cypermethrin. Fifty-one partial sequences of P450 genes were identified in transcriptome data, and 15 of them were fully sequenced. With the progress of cloning, a solid basis would be made for the identification of their diversity and detoxification of insecticides. Now, accomplishment of genome project of B. dorsalis provides an opportunity to get a comprehensively understanding of its resistance mechanism, and will improve the resistance management of this pest.

The effects of Xanthotoxin on some biochemical parameters of *Galleria mellonella* (Lepidoptera: Pyralidae)

Meltem Erdem[1], Ender Buyukguzel[2]

[1]Zonguldak Karaelmas Unıversity, Turkey, [2]Zonguldak Karaelmas Unıversity, Turkey

The effects of a plant allelochemical, xanthotoxin (XA), on important oxidative stress indicators, lipid peroxidation product, malondialdehyde (MDA) and protein oxidation products, protein karbonyl (PCO) contents and a detoxification enzyme glutathione-S-transferase (GST) activity were investigated in the adults of the greater wax moth Galleria mellonella (L.). The insect was reared from first-instar larvae on an artificial diets containing XA at 0.001, 0.005 or 0.1% to adult stage in the laboratory condition. The lowest concentration of XA (0.001%) significantly increased MDA content from 0.005 ± 0.0005 to 0.028 ± 0.001 nmol/mg protein by approximately 6-fold while it had no significant effect on protein carbonyl content and GST activity. XA at high concentrations (0.005 and 0.1%) significantly increased MDA (3-fold) and protein carbonyl (2-fold) contents while they significantly resulted in decreased GST activity. The highest dietary XA concentration significantly decreased GST activity from 0.276 ± 0.025 to 0.159 ± 0.005 µmol/mg protein/min. Two of the markers indicated that significantly higher levels of oxidative stress were produced in the whole body of adult reared on diets supplemented with XA. This oxidative stress was associated with elicited detoxification responses by markedly decreasing GST activities in adults. We infer from these findings that XA-induced oxidative stress exerted strong inhibitory effect on the activity of the wax moth detoxification enzyme leading to decreased adult fitness.

Effects of ethacrynic acid on characterizations of GSTs from *Liposcelis bostrychophila*

Jingjing Wu[1], Dandan Wei[2], Wei Dou[3], Jinjun Wang[4]

[1]Southwest University, China, [2]Southwest University, China, [3]Southwest University, China, [4]Southwest University, China

Glutathione S-transferases (GSTs) are a large family of multifunctional enzymes found ubiquitously in aerobic organisms. In order to clarify the effects of ethacrynic acid (EA) on the biochemical and toxicological characterizations of GSTs from Liposcelis bostrychophila (Psocoptera: Liposcelididae), GSTs from the psocid rearing on the diet with 0.5% EA or 3% EA for 30 days was purified by glutathione-agarose affinity chromatography, and characterized subsequently by their Michaelis-Menten kinetics toward the artificial substrates 1-chloro-2,4-dinitrobenzene (CDNB) and reduced glutathione (GSH). The bioassay results revealed that the psocids on the diets including different contents of EA both exhibited more sensitivity to deltamethrin compared to the control, the psocids on the normal diet. The specific activity of the affinity of purified GST toward CDNB was highest in the control, 1.87- and 10.00- fold higher than the counterparts of the psocids on 0.5% and 3% EA diets, respectively. GSTs of psocids after EA treatment exhibited lower maximal velocity values for both the substrates above than that of control. However, the apparent Michaelis-Menten constants differed a lot with higher values for the substrated GSH while lower for CDNB, revealing EA treatment induced GSTs to express a significant lower affinity to the GSH. Inhibition kinetics showed that all test compounds (EA, diethyl maleate, and deltamethrin) possessed significant inhibitory effects on GSTs and the enzyme indicated less sensitivity to the compounds after continous EA treatment.

Stress response and metabolomic defects in apoptosis-deficient mutant in *Drosophila melanogaster*

Fumiaki Obata[1], Erina Kuranaga[2], Asuka Takeishi[3], Ming Ming[4], Tomoyoshi Soga[5], Masayuki Miura[6]

[1]the University of Tokyo, Japan, [2]RIKEN CDB, Japan, [3]the University of Tokyo, Japan, [4]the University of Tokyo, Japan, [5]Keio University, Japan, [6]The University of Tokyo, Japan

Multicellular organisms have evolved machineries for tissue remodeling to get rid of damages by apoptosis resulted from environmental stresses. Apoptosis is a programmed cell death, which is executed by evolutionary-conserved cysteine proteinases, caspases. Because tissue remodeling is essential for any organisms to maintain homeostasis, dysregulation of apoptosis leads to major pathologies such as cancer. There is increasing evidence that apoptotic machinery is correlated with inflammation, proliferation, and metabolic homeostasis, which are also altered in cancer cells. However, it is not known so far what occurred practically in vivo if apoptosis is defective. In this study, we focused on stress response and metabolic alteration in Drosophila apaf-1 (dark/hac-1/dpf-1) hypomorphic mutant, in which caspase activation and subsequent apoptosis were severely impaired. We found that dpf-1 mutant was sensitive to starvation- and oxidative-stress. Starvation susceptibility was resulted from "wasting" phenotype as revealing their shortage of energy storage. Next, we conducted metabolomic analysis of hemolymph in dpf-1 mutant using capillary electrophoresis-mass spectrometry (CE-MS) system to investigate the physiological consequences of apoptosis defects. Several metabolites were increased in dpf-1 mutant, which was likely due to the alteration of expression level of putative metabolic enzymes in fat body at least for one of such metabolites. We have succeeded in modulating the level of the metabolite through genetic manipulation of metabolic enzymes and tested whether alteration of metabolite affected stress sensitivity. We will present and discuss the physiological role of apoptosis based on investigation of metabolic alteration in dpf-1 mutant.

Winter climate change: Elevated adult temperature results in epigenetic loss of cold tolerance in overwintering larvae of the blowfly, *Calliphora vicina*

Paul Christopher Coleman[1], Jeffery S Bale[2], Scott A L Hayward[3]

[1]University of Birmingham, United Kingdom, [2]University of Birmingham, United Kingdom, [3]University of Birmingham, United Kingdom

As ectotherms, insects are particularly vulnerable to global warming. Current rates of warming have altered the phenology and distribution of numerous insect species, while virtually nothing is known about how global warming has affected the ability of insects to successfully overwinter. This is surprising, as winter periods with limited nutrients and periods of extreme cold are the most challenging for temperate insects. Virtually all temperate insects utilise diapause as their overwintering strategy. Typically this is initiated by change in an environmental cue. For example in Calliphora vicina adult females detect shortening photoperiod, signalling the advent of winter, while their progeny overwinter as diapausing larvae. Global warming threatens to expose adults to warmer late-autumn temperatures, while diapausing larvae will still experience periods of severe mid-winter cold. The effect this will have on the epigenetic inheritance of cold tolerance was investigated by culturing adults at 15 and 20ºC and assessing cold tolerance in their progeny. It was found that adults cultured at higher temperatures produced diapausing progeny with a less intense diapause, reduced supercooling ability and increased mortality following exposure to -4 and -8ºC. This provides evidence that warmer late-autumn temperatures may result in reduced cold tolerance and therefore elevated mortality in the diapausing life-stage. Interestingly the effect of adult thermal history was not detected in cold tolerance of non-diapause larvae, indicating the cross-generational programming of diapause is closely linked to cold tolerance. Underlying mechanisms are still to be identified but may involve altered lipid-membrane composition or altered expression of heat-shock proteins.

Apoptosis and autophagy in the midgut of the American cockroach, *Periplaneta americana* under short-term and long-term starvation

Moon Soo Park[1], Pyoyun Park[2], Makio Takeda[3]

[1]Kobe University, Japan, [2]Kobe University, Japan, [3]Kobe University, Japan

Short-term starvation, of 2 weeks, does not affect mortality in Periplaneta americana. However long-term starvation, of 4 weeks, reduced the number by half and affected the midgut structure, inducing many small condensed nuclei in the nidi, nests of stem cells and newborn cells. Apoptosis often exhibits nuclear condensation with chromatin concentration. Autophagy, a self-digestion, may be induced in the midgut of the starved cockroaches but it is unclear whether short or long-term starvation stimulates autophagy. This study investigates effects of short or long-term starvation on apoptosis and autophagy in the midgut of P. americana, histochemically, ultrastructurally, and at molecular biology level. During short-term starvation, cell death began to increase in the columnar cells. However long-term starvation reduced the cell population and showed a significant increase in cell death in the nidi. The cell death in the nidi was apoptosis because of the active-caspase 3-like immuno-reactivity and chromatin condensation under electron microscopic observation. Translation and activation of specific autophagic marker, ATG8 was stimulated drastically in long-term starvation. These results suggest that short-term starvation gradually increased the cell death in the midgut epithelium, whereas long-term starvation induced apoptosis in the nidi and autophagy in the midgut. P. americana probably shift the defense mechanism according to the progression of starvation from optimistic conditions to emergency situations.

Flight performance of bumblebees under Mars' micro gravity (0.38G)

Masami Sasaki[1], Katsuya Hasegawa[2], Masamichi Yamashita[3]

[1]Tamagawa University, Japan, [2]Japan Aerospace Exloration Agency, Japan, [3]Japan Aerospace Exploration Agency, Japan

Flight performance of bumblebees (Bombus ignitus) under micro gravity was studied using parabolic flight of Jet plane (MU-300), to see if the bumblebees can fly under zero or micro gravity (such as in Int. Space Station), or under the Mars' gravity (=0.38G). Various strength of micro gravity condition was made by parabolic flights (ca 30s x 10 to 12 times per flight) and the bees in flight chambers were triggered to fly by the onset of illumination with UV-LED. The number of bees kept in a chamber was ca 25 in a big one (30 x 30 x 30 cm), 3 in a small one (15 x 20 x 5cm in depth). Each chamber (one large and 3 small ones) was monitored by different type of video recorders including high speed of 250 flames per second. The bees could take off and began to fly but could not fly normally in 0G. They fly with high speed after few strokes of wings and hit the chamber wall. But under 0.38G, they tried to keep balance in hovering-like motion during their flight. We could not confirm whether they can fly in long distance or long duration, because the duration of controlled micro gravity was 30 seconds in maximum in this experiment. The evidence suggests that the bumble bees can be used in future as possible pollinator in the crop production in Mars.

Oxidative stress is a major factor for the induction of anhydrobiosis in the desiccation-tolerant midge, *Polypedilum vanderplanki.*

Richard Cornette[1], Ken-ichi Iwata[2], Yasushi Kanamori[3], Oleg Gusev[4], Takahiro Kikawada[5], Takashi Okuda[6]

[1]National Institute of Agrobiological Sciences, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]National Institute of Agrobiological Sciences, Japan, [4]National Institute of Agrobiological Sciences, Japan, [5]National Institute of Agrobiological Sciences, Japan, [6]National Institute of Agrobiological Sciences, Japan

In the semiarid regions of Africa, larvae of the sleeping chironomid (Polypedilum vanderplanki) are able to survive in a completely desiccated state without any metabolic activity throughout the dry season, which may last for 8 months. This phenomenon is known as anhydrobiosis. Upon rehydration, dry larvae can recover normal activity in less than one hour. In order to identify genes involved in the anhydrobiosis of P. vanderplanki, EST libraries were constructed from normally active, desiccating and anhydrobiotic larvae. EST and microarray analyses showed the up-regulation of desiccation responsive genes, such as antioxidants, Late Embryogenesis Abundant (LEA) proteins, HSPs, transporters and trehalose synthesizing enzymes, during the induction of anhydrobiosis. Oxidative stress was apparently a major damaging factor during anhydrobiosis and in spite of the up-regulation of many antioxidant genes, rehydrating larvae experienced severe oxidative damage on proteins, DNA and biological membranes. Microarray analysis of larvae treated with the oxidative reagent Paraquat (PQ) showed that in addition to the classical antioxidant response, general desiccation-related gene expression was also observed after treatment, suggesting that apart from their harmful effect, reactive oxygen species (ROS) can also act as important signaling molecules. Functional analyses using PQ and an antioxidant confirmed that ROS were directly involved in the regulation of gene expression during the induction of anhydrobiosis. We propose that the oxidative stress response pathway has been co-opted for the induction of anhydrobiosis in P. vanderplanki and further functional analyses will focus on the genes involved in ROS sensing.

Frost expression is not essential for recovery from chill coma, acute cold tolerance, and rapid-cold hardening in *Drosophila melanogaster*

Hiroko Udaka[1], Anthony Percival-Smith[2], Brent Sinclair[3]

[1]University of Western Ontario, Canada, [2]University of Western Ontario, Canada, [3]University of Western Ontario, Canada

Temperature affects many physiological processes in insects and surviving winter sub-zero temperatures is critical for many insects in temperate and polar zones. Cold tolerance in insects is enhanced not only by long term acclimation to low temperature, but by short periods of non-lethal cold exposure, rapid cold-hardening (RCH). Although some previous studies have reported physiological processes of the RCH response, the mechanisms underlying RCH are still not clear. Frost is up-regulated during recovery from cold exposure in D. melanogaster. Previous work showed that knockdown of Frost increases chill-coma recovery time, but the role of Frost in acute cold tolerance and RCH remains unknown. To clarify the contribution of Frost to cold tolerance, we used several D. melanogaster lines with Frost expression knocked-down with the GAL4/UAS system and obtained lines with varying Frost expression levels. Chill-coma recovery time, survival rate after acute cold exposure and RCH were measured in each line. There was no correlation between gene expression levels and three different types of cold tolerance, suggesting that Frost is not essential for those cold tolerance phenotypes.

Influence of hexane extract of *Ocimum sanctum* on longevity and reproduction of *Dysdercus koenigii*

Sunil Kayesth[1], Kamal Kumar Gupta[2]

[1]*University of Delhi, India,* [2]*University of Delhi, India*

Impact of Hexane extract of Ocimum sanctum, was evaluated on longevity and reproduction of Dysdercus koenigii. Sexually mature adults and 5th instars were treated with 10%, 5%, 2.5% and 1.25% of hexane extract of Ocimum leaves. When adults were treated with 10% extract mortality was 100% and they died on an average within 4 days. 5% of hexane extract was more toxic to males than the females. Also the longevity of the treated males was lesser than the treated females. A concentration of 2.5% and 1.25% did not affect longevity of the insect significantly. The hexane extract of Ocimum has profound effect on the mating behavior of Dysdercus. The adults when treated with 5%, 2.5% and 1.25% of hexane extract exhibited disruption of courtship behavior. As a result mounting attempts and successful mating rate was reduced. This is in contrast to normal adults which mate immediately after releasing in to the jars. The extract also altered oviposition behavior of the females. The treated females laid lesser number of egg batches, number of eggs in each egg batch and total number of eggs laid in their entire lifespan. The eggs laid by treated females had lower hatching success. When fifth instars were treated with Ocimum leave extract their moulting success was decreased. They retained nymphal characters or turned in to adultoids after moulting. There was a direct correlation in concentration of extract and the deformities observed in the fifth instar nymphs The supranumeric instars and adultoids failed to mate and reproduce.

Determination of catecholamines and aminoacids from venom reservoir extract of honeybee (*Apis*) species

Nallahalli Shivarajegowda Surendra[1], Gopasandra Narayanappa Jayaram[2], Muniswamyreddy Shankar Reddy[3]

[1]Bangalore University, India, [2]Bangalore University, India, [3]Bangalore University, Jnana Bharathi, Bangalore-560056, India

Catecholamines system plays a variety of roles in animals, as neurotransmitters, neuromodulators, hormones, paracrine and autocrine factors. Neumerous venoms of widely different animals have evolved to manipulate these systems for both defensive and offensive purposes of the venomous animals. Catecholamines are sympathomimetic and comprises of catechol group derived from the amino acid thyrosine. Amino acids are essential building blocks of proteins and peptides. Physiological and anatomical evidence suggests that certain amino acids act as neurotransmitters of the major excitatory or inhibitory commands in the central nervous system and also take part in intermediary metabolism. The catecholamines viz., epinephrine (E), norepinephrine (NE), dopamine (D), 3,4 dihydroxyphenyl acetic acid (DOPAC), 5- hydroxyindole-3-acetic-acid (5-HIAA), 5- Hydroxytryptamine (5HT) and 4-hydroxy-3-methoxy-phenylacetic acid (HVA) were quantified from venom gland with reservoir extract of Apis cerana, Apis dorsata and Apis florea using Liquid chromatography with electrochemical detection (ECD) method. The quantitative results showed species dependent variation. The other two vital bioactive components examined namely DOPAC and HVA were absent in the three examined honey bee species and 8 amino acids (Aspartate, Glutamate, Serine, Alanine, Glysine, Phenyl ethanolamine, GABA and Tyrosine) were analysed to compare their presence in venom of three Apis species viz., A. dorsata, A. cerana, A. florea. All the 8 amino acids assayed were present in all the three species but the quantity of each amino acid differed in the venoms from different species of honeybees.

Oxygen limitation of thermal tolerance in aquatic insects

David T. Bilton[1], Wilco C. E. P. Verberk[2]

[1]Plymouth University, United Kingdom, [2]Plymouth University, United Kingdom

Thermal limits may arise through a mismatch between oxygen supply and demand in a range of animal taxa. This oxygen limitation hypothesis is supported by data from a range of marine organisms butit is unclear whether oxygen limitation determines thermal extremes in tracheates including insects. We demonstrate that thermal limits do indeed respond to external oxygen supply in the aquatic life stages of Plecoptera, suggesting that the critical thermal limits of such aquatic larvae are set by oxygen limitation. These findings have implications for our understanding of the limits to insect body size and how these are influenced by atmospheric oxygen levels, and indeed a larval view of Palaeozoic insect gigantism may be very informative, explaining the predominance of aquatic life stages amongst giant insects.

Changes in energy metabolites as well as body color phenotypes for starvation and desiccation resistance in montane populations of *D. melanogaster*

Dau Dayal Aggarwal[1], Ravi Parkash[2]

[1]M.D.University, India, [2]M.D.University, India

Storage of energy metabolites have been investigated in different sets of laboratory selected desiccation or starvation resistant lines but few studies have examined such changes in wild-caught populations of D. melanogaster. In contrast to parallel selection of desiccation and starvation tolerance under laboratory selection experiments, opposite clines were observed in wild populations of D. melanogaster. We tested whether there is a trade-off for storage as well as actual utilization of energy metabolites in D. melanogaster altitudinal populations. For desiccation resistance, darker flies store more body water content and endure greater loss of water as compared to lighter flies. Based on within population analysis, we found evidence for coadapted phenotypes i.e. darker flies store and actually utilize more carbohydrates to confer greater desiccation resistance. In contrast, higher starvation resistance in lighter flies is associated with storage and actual utilization of greater lipid amount. However, darker and lighter flies did not vary in the rate of utilization of carbohydrates under desiccation stress; and of lipids under starvation stress. Thus, we did not find support for the hypothesis that a lower rate of utilization of energy metabolites may contribute to greater stress resistance. Further, for increased desiccation resistance of darker flies, about two-third of total energy budget is provided by carbohydrates. By contrast, lighter flies derive about 66% of total energy content from lipids which sustain higher starvation tolerance. Our results support evolutionary trade-off for storage as well as utilization of energy metabolites for desiccation versus starvation resistance in D. melanogaster.

Discovery of woolly apple aphid *Eriosoma lanigerum* (Hemiptera: Aphididae) biotypes in Australia

Arnaud Costa[1], David Williams[2], Kevin Steven Powell[3]

[1]Department of Primary Industries, Australia, [2]Department of Primary Industries, Biosciences Research Division, Australia, [3]DPI-Victoria, Australia

The woolly apple aphid (WAA), Eriosoma lanigerum Hausmann (Hemiptera: Aphididae), is a worldwide pest of apple orchards that has become widespread in Australia. Several populations of this pest insect that are geographically distant may have evolved into distinct biotypes having different parameters of fitness (e.g. fecundity) on the same food source. In this study, we investigated the performance of four different lines of WAA (ALB, STA, BAT, and YAR) originating from four different locations of Victoria and New South Wales. Each line was grown from a single apterous female. In a glasshouse trial, we monitored the percentage of nymphs that established after 7 days, the percentage of nymphs that successfully reach the adult stage, the nymph developmental time on whole apple trees (cv. Granny Smith). We also measured adult weight and female fecundity. Our results showed that the four lines of WAA examined in the scope of this study can exhibit significant differences either in establishment success or in fecundity. Female fecundity, adult weight and developmental time were significantly higher in STA relative to ALB, while there was no significant difference of establishment success between these two biotypes. However, establishment of YAR was the lowest (42%) compared to biotype STA (64%). Our results demonstrate the existence of at least three different biotypes of WAA in Australia. Antibiosis and antixenosis could explain respectively the differences in aphid establishment and in fecundity of WAA biotypes. The discovery of WAA biotypes can have major implications for the management of this pest.

Aphid alarm pheromone: Recent advances on biosynthesis and functions

Sophie Vandermoten[1], Eric Haubruge[2], Frederic Francis[3]

[1]University of Liege - Gembloux Agro-Bio Tech, Belgium, [2]University of Liege - Gembloux Agro-Bio Tech, Belgium, [3]University of Liege - Gembloux Agro-Bio Tech, Belgium

Aphids are among the most abundant and destructive insect pests of agriculture, particularly in temperate regions, causing direct damage to arable and horticultural crops as well as serving as vectors for many important plant diseases. As with most other insect interactions, the signals that mediate conspecific interactions among aphids are primarily chemical; and the most prominent and well-studied interactions among aphids are those mediated by "alarm" pheromones. The aphid alarm pheromone - of which the sesquiterpene (E)-β-farnesene is the key (or only) component in most species - plays important roles in mediating interactions among individuals as well as multitrophic interactions among plants, aphids, and aphid natural enemies. The alarm pheromones of several aphid species have been isolated and identified and, though many important questions remain to be answered, a large body of research has addressed various aspects of the biology, physiology, and ecology of aphid alarm pheromones (as recently reviewed by Vandermoten et al. in Insect Biochemistry and Molecular Biology 42 (2012) 155-163). Especially, we contributed to recent advances in the understanding of aphid alarm pheromone biosynthesis by the characterization of aphid prenyltransferases producing both geranyl diphosphate and farnesyl diphosphate which are the precursors of mono- and sesquiterpenes, respectively. The information gained from a deeper understanding of the biosynthesis and regulation of aphid alarm pheromone as well as the chemical ecology of aphid-natural enemy interaction will enhance our understanding of the biology and ecology of aphids and may facilitate the design of novel control strategies.

Analysis of the yolk proteins expression in the male reproductive system of *Drosophila melanogaster*

Piotr Bebas[1], Magdalena Maria Majewska[2], Agnieszka Suszczynska[3], Joanna Kotwica-Rolinska[4], Marta Anna Polanska[5]

[1]Uniwersity of Warsaw, Poland, [2]Uniwersity of Warsaw, Poland, [3]Uniwersity of Warsaw, Poland, [4]University of Warsaw, Poland, [5]University of Warsaw, Poland

Egg storage proteins (YP's) are produced in the female fat body and ovary and participate in egg maturation. This class of proteins is not expressed in males under physiological conditions. In this study we demonstrate that the male reproductive system of Drosophila melanogaster most likely produces yolk proteins under normal conditions. Using 2-D electrophpresis and protein sequencing, we obtained sequences that are homologous to yolk proteins 1 and 2 in male reproductive system. We examined the presence of these proteins in the testes and tissues of the male reproductive tract using an antibody against YP's in immunocytochemical and Western blot analysis. Our results show that the YPs are present in testes, luminal fluid and accessory glands. In addition, they are also present on the surface of sperm from the seminal vesicles. We prove that their level changes in a rhythmic manner - this rhythm persists in light/dark cycles. Our findings suggest that yolk proteins are most probably expressed in cyst cells in the testes and accessory glands, transported with the fluid to the seminal vesicles and bind to sperm in this organ. Supported by NCN Grant No. N N303 595639 to P.B.

Differential gene expression between fat body of male and female in oriental fruit fly, *Bactrocera dorsalis*

Mei-Er Chen[1], Yu-Han Zuo[2]

[1]*National Chung Hsing University, Taiwan,* [2]*National Chung Hsing University, Taiwan*

The fat body plays many roles in insects. Most hemolymph proteins are synthesized in the fat body. The gene expression differences of fat body between 8-, 9-, and 10-day old male and female Bactrocera dorsalis were performed using the suppression subtractive hybridization method. 993 male specific clones were partially sequenced and searched using BLAST. About 21 % of these clones showed homology with detoxification enzymes including cytochrome P450s (Cyps) and glutathione S-transferases (GSTs). NADH dehydrogenases and storage protein receptor (SPR) which distributed to energy metabolism constituted about 16 % of these clones. About 9 % of these clones were antimicrobial peptides (AMPs). Cyp, GST, NADH dehydrogenase, SPR and AMP were also probed for microarray assay. Both microarray assay and real-time quantitative PCR showed that the five transcripts were expressed at higher levels in fat body of male than that of female. These results suggested while yolk protein synthesis is the main function of fat body in female, Cyp, GST, NADH dehydrogenase, SPR and AMP play important roles in male for its survival.

Molecular cloning, expression patterns and RNAi analysis of vitellogenin receptor from the brown planthopper, *Nilaparvata lugens* (Stal)

Kai Lu[1], Qiang Zhou[2]

[1]*Sun-Yat-sen University, China,* [2]*Sun-Yat-sen University, China*

The brown planthopper (BPH), Nilaparvata lugens, is the most destructive pest of rice throughout Asia. The vitellogenin receptor (VgR) mediates the uptake of vitellogenin (Vg) into developing oocytes during egg formation in insects. In this study, the cDNA of N. lugens VgR (NlVgR) was cloned and sequenced. The full-length cDNA of NlVgR is 6174 bp with an open reading frame of 5796 bp, encoding a protein of 1931 amino acids. Quantitative real-time PCR (RT-qPCR) and Reverse Transcription- PCR (RT-PCR) analyses revealed that NlVgR mRNA was specifically expressed in ovarian tissues. The developmental expression profiles showed that NlVgR mRNA was first transcripted in 1st day of brachypterous adults and reached the highest level on 9th day. Western blot analysis detected an ovary-specific VgR protein with a MW of ~215 kDa and protein temporal profiles were the same as mRNA expression patterns. RNA interference (RNAi) showed that 1st day of brachypterous adults injected with 100 or 250 ng VgR-dsRNA disrupted egg formation and significantly decreased the number of offspring. Western blot revealed that vitellogenin (Vg) concentration in haemolymph was increased and Vg content in ovary was decreased. NlVg mRNA expression level and total Vg protein content of whole body were not changed. These results show that VgR mediate the incorporation of Vg into oocytes during egg development and plays a crucial role in reproductive process of the BPH .

Fenoxycarb induced disturbance of testes development, apoptosis of germ cells and sperm release in moths

Marta Anna Polanska[1], Michalina Kamut[2], Joanna Kotwica-Rolinska[3], Piotr Bebas[4]

[1]Uniwersity of Warsaw, Poland, [2]University of Warsaw, Poland, [3]Uniwersity of Warsaw, Poland, [4]University of Warsaw, Poland

Application of fenoxycarb, a potent juvenile hormone analogue (JHA) belonging to insect growth regulators (IGR), induces different morphological, physiological and behavioral changes during development and metamorphosis of insects. The administration of fenoxycarb to Galleria mellonella larvae blocks metamorphosis, causing a significant elongation of larval development and leading to supernumerary larval instars. In many studies authors indicate the strong influence of fenoxycarb on the reproduction in females. In this study we present the effect of fenoxycarb on male reproductive system in Galleria mellonella larvae. Effect of JHA on the structure of testes and spermatogenesis was analyzed for 28 days since fenoxycarb administration, until larval-pupal intermedians or deformed pupae appeared. Characteristic feature of male reproductive system is fusion of paired testes into one organ, present in adult males. In insects treated with the juvenoid, testicular fusion does not occur, and a portion of the spermatocytes is eliminated through apoptosis. The spermatocytes, which are developmentally advanced, enter the stage preceding the first meiotic metaphase and then degenerate in the process restricted to several characteristic events. We observed nuclear envelope disruption, an aberrant nucleus containing heterochromatic bodies seen as an electron-dense material, and finally the lysis of whole cells. The histochemical study demonstrates that all of these processes are of an apoptotic character. Another aspect of our study was the effects of fenoxycarb on sperm release in adult males of two lepidopterans, mentioned above Galleria mellonella and Spodoptera littoralis, model organism for circadian research. Supported by NCN grant No. N N303 803340 to MAP.

Studies on reproductive behaviour of susceptible and insecticide-resistant *Plutella xylostella* (Linnaeus)

Anureet Kaur[1], Gursharan Singh[2]

[1]*Punjab Agricultural University, India,* [2]*Punjab Agricultural University, India*

Diamondback moth (DBM), Plutella xylostella (Lepidoptera: Plutellidae) is cosmopolitan and most noxious pest of cruciferous crops and has developed resistance to more than 46 insecticides including those with novel modes of action. One of the mechanisms of insecticide resistance is behavioural mechanism and was studied w.r.t. reproductive behaviour of P. xylostella. Influence of the test-insecticides was observed on various reproductive parameters of P. xylostella by allowing the freshly emerged adults to mate in four different combinations i.e. resistant male mated with resistant female (RM×RF), resistant male mated with susceptible female (RM×SF), susceptible male mated with resistant female (SM×RF) and susceptible male mated with susceptible female (SM×SF).No significant difference was observed among the various combinations as regards pre-oviposition and post-oviposition period. Oviposition period, however differed significantly for RM×RF i.e. 8.33 days. Hence, the maximum fecundity was recorded for RM×RF i.e. 185.0 and was significantly more than all the other three combinations. It is noteworthy that highly appreciable reduction of the egg-size (0.023 mm3) was recorded in the combination RM×RF. An egg-size of 0.035 mm3 was recorded for combination SM×SF which was significantly more than the other combinations. Reproductive effort (fecundity × egg-size) was compared for all the four combinations and no significant difference was noted. Hatchability of the eggs from the combination SM×SF (79.28 %) was significantly more than that RM×RF combination where it was 74.10 percent.

Effects of hen egg white proteins on reproductive performance of red flour beetle, *Tribolium castaneum* (Coleoptera:Tenebrionidae)

Megha Kansal[1], Geetu Choudhary[2], Ranjit Kaur Parshad[3]

[1]Punjab Agricultural University, India, [2]Punjab Agricultural University, India, [3]Punjab Agricultural University, India

Tribolium castaneum (Herbst), being among the most adaptive and problematic pest of stored-products. Hen egg white comprises growth inhibiting dietary proteins against many Coleopteran species and moths. Therefore, the present work describes the evaluation of insecticidal activity of egg white proteins on the reproductive parameters of Tribolium castaneum. Protein samples obtained through salt fractionation (PPT-I and PPT-II) including whole egg white (WEW) were lyophilized. Different concentrations (2%, 3%, 4%, 5%, 10%) of each of the protein samples were tested by adding them to wheat flour and milk powder (75:25 w/w). The fecundity rate, reproductive effort of the beetles were significantly ($p<0.05$) lower in 3%, 4%, 5% and 10% of both PPT-I and PPT-II than that of the control group after 30 days of treatment. Marked abnormalities were observed in appearance and dimensions of ovarioles and eggs which indicated that the egg protein samples caused considerable effect on the process of oogenesis. Scanning electron microscopy studies revealed changes in the structure of epithelial sheath cells of ovarioles probably caused due to resorption of ova in the beetles fed on PPT-II proteins. Higher resolution of the egg surface showed the presence of wrinkles or shrivelled appearance of the chorionic layer in PPT-I and PPT-II treated eggs and these deep folds were more conspicuous in the beetles fed on PPT-II proteins. The findings reveal that hen egg white proteins could reduce the general fitness of an insect and thus the reproductive capacity.

Male calling and the reflex arc In *Leptophyes punctatissima*

David John Robinson[1], Patricia Ash[2], Marion Hall[3]

[1]The Open University, United Kingdom, [2]The Open University, United Kingdom, [3]The Open University, United Kingdom

The flightless bushcricket Leptophyes punctatissima has a widespread distribution in Europe. Males and females communicate using ultrasound and the speed of communication is so fast that the neural circuit involved in the female reply to the male call is a reflex arc. The height at which males call, the sites they choose and the auditory and ecological problems that these pose, are part of a long-term study of acoustics and mate choice in this unusual species. Observations on adult mating behaviour were made at night, adults being located using directional ultrasound detectors. The approximate position of singing individuals was determined using paired detectors linked to an oscilloscope and the height of the singing male above the ground was calculated. Males were recorded at a range of heights between ground level and 14 m, a substantial height for a small flightless bush cricket. The choice of singing sites, the use of very short signals and the speed of reply of the females will be discussed in the context of the mating behaviour of this species together with the underlying neural pathway in the female.

Olfactory and gustatory receptor genes in *Trissolcus basalis*

Elijah Talamas[1], Norman F. Johnson[2]

[1]*The Ohio State University, U.S.A.*, [2]*The Ohio State University, U.S.A.*

Trissolcus basalis (Hymenoptera: Platygastridae) is an important egg parasitoid in the biological control of stinkbugs, including Nezara viridula (Pentatomidae). Gustatory (Gr) and odorant (Or) receptors proteins are components of the insect chemosensory system that bind to odor molecules and induce neuronal signalling. The structure of these proteins is thought to determine their ligand-binding properties, conferring the ability to detect kairomones and locate host eggs. These genes are subject to extensice duplication and loss, and likely play an important evolutionary role in shifts of host choice and speciation. Here we present annotation of gustatory and odorant receptor genes in T. basalis as the first step in a project to understand how gene evolution affects host choice and speciation within the genus Trissolcus. We compare our results with the arrays of Or and Gr genes in Apis mellifera, Nasonia vitripennis (Hymenoptera.: Pteromalidae), and 4 species of ants.

Olfactory conditioning in the German cockroach

Jiali Liu[1], Masayuki Sakuma[2]

[1]Kyoto university, Japan, [2]Kyoto university, Japan

The German cockroach is an important pest in association with humans world-wide. Various food odors were used as bait attractants to control them. It is believed that the cockroaches locate food by remembering learned general odor, so we could exploit this nature for an efficient control of the pest. In this study, we investigated the capability of learning and memory in the German cockroach. Firstly we carried out a differential type conditioning by presenting (-)-menthol odor with sucrose solution reward, followed by vanillin odor with saline punishment. Cockroaches exhibited apparent preference to the rewarded (-)-menthol rather than punished vanillin odor after three trials, and induced memory retention for 1-day. Then we simplified the conditioning procedure to analyze the causation of cockroach attractiveness to the rewarded odor. We conducted an elemental conditioning by associating a (-)-menthol or vanillin odor with sucrose reward or saline punishment independently. Increase or decrease in the number of animal visits to the odor source evaluates the results. The number increased after (-)-menthol was presented with reward, while it did not change for rewarded vanillin odor. In both odors, the number decreased significantly after training with saline punishment. These results indicate that cockroaches learn a single odor presented as a conditioned stimulus, although association of odor with reward or punishment depends largely on the chemical. This simplified olfactory conditioning procedure enables further analysis of cockroach searching behavior evoked by a learned general odor.

Expression profiles and functional study of three odorant binding proteins in *Nilaparvata lugens* Stal

He Peng[1], Shuang-Lin Dong[2]

[1]*Nanjing Agricultural University, China,* [2]*Nanjing Agricultural University, China*

Odorant binding proteins (OBPs) play important roles in insect olfaction. The brown planthopper (BPH), Nilaparvata lugens Stal (Delphacidae , Auchenorrhyncha, Hemiptera) is one of the most important rice pests. Its monophagy (only feeding on rice), wing form (long and short wing) variation, and annual long distance migration (seeking for rice plants of high nutrition) imply that the olfaction would play a central role in BPH behavior. However, the olfaction related proteins have not been characterized in this insect. In this study, full length cDNAs of three OBPs were obtained by combination use of homologous searching of thranscriptomic data and RACE techniques, and distinct expression profiles were revealed regarding to tissue, developmental stage, wing form and gender for the first time for the species. Further binding assays with 41 compounds demonstrated that NlugOBP3 had markedly higher binding ability and wider binding spectrum than the other two OBPs. Terpenes and Ketones displayed higher binding while Alkanes showed no binding to the three OBPs. Focused on NlugOBP3, RNA interference experiments showed that NlugOBP3 not only involved in nymph olfaction on rice seedlings, but also had non-olfactory functions, as it was closely related to nymph survival. Therefore, it might serve as a potential target for developing behavioral disruptant and/or lethal agent in N. lugens.

Differential localization of splice variants of a glutamate-gated chloride channel subunit in the housefly

Tomo Kita[1], Fumiyo Ozoe[2], Masaaki Azuma[3], Yoshihisa Ozoe[4]

[1]Tottori University, Japan, [2]Shimane University, Japan, [3]Tottori University, Japan, [4]Shimane University, Japan

L-Glutamic acid (glutamate) functions as both excitatory and inhibitory neurotransmitters in the nervous system of invertebrates. The action as the inhibitory neurotransmitter is mediated by glutamate-gated chloride channels (GluCls), which are formed by five subunits encoded by a single gene. It is important to study the physiological roles and the pharmacological properties of GluCls as they are considered important targets for insecticides. In this study we first performed quantitative PCR (qPCR) and immunohistochemical analysis to examine the tissue localization of GluCls in the housefly (Musca domestica L.). The results indicated that GluCls were primarily localized in the optic lobe of the adult head. They were also distributed in the somata of the motor neurons of the thoracic ganglion and nerve fibers in the leg. As alternative splicing of pre-mRNA generates three exon-3 splice variants (A, B, and C) of the GluCl subunit, we next performed qPCR analysis to investigate the expression level of each variant in the adult housefly. The transcripts of variants A and B were primarily expressed in the head, whereas that of variant C was predominantly detected in peripheral tissues such as the leg and the abdomen. When heterologously expressed in Xenopus oocytes, the three variant channels did not show significant differences in sensitivity to glutamate and the maximal amplitude of currents evoked upon activation by glutamate, although the expression levels of three variant channels in Xenopus oocyte were different. These findings suggest that GluCl variants participate in signal transduction in different regions of the housefly.

Sequencing and characterizing odorant receptors sensitive to the pheromones of the Cerambycinae (Coleoptera: Cerambycidae)

Robert F. Mitchell[1], David T. Hughes[2], Charles W. Luetje[3], Jocelyn G. Millar[4], Lawrence M. Hanks[5], Hugh M. Robertson[6]

[1]University of Illinois at Urbana-Champaign, U.S.A., [2]University of Miami, U.S.A., [3]University of Miami, U.S.A., [4]University of California, Riverside, U.S.A., [5]University of Illinois at Urbana-Champaign, U.S.A., [6]University of Illinois at Urbana-Champaign, U.S.A.

Many species of longhorned beetles (Cerambycidae) rely on volatile pheromones to locate mates. Pheromones within subfamilies and genera may be highly conserved, and many species produce similar or identical compounds. In the subfamily Cerambycinae, the chemicals 3-hydroxyhexan-2-one, 2,3-hexanediol, and 2-methyl-1-butanol are produced as pheromones by many dozens of species. We are studying the pheromone receptors of the Cerambycinae to better understand the evolution of this unusual overlap of pheromones. We sequenced an antennal transcriptome of the longhorned beetle Megacyllene caryae (Gahan), which produces in its pheromone blend the common cerambycine pheromones 2,3-hexanediol and 2-methyl-1-butanol, and characterized odorant receptors sensitive to these two pheromones as well as an additional pheromone, 2-phenylethanol. We used degenerate primers to isolate potential orthologs of these receptors from the congener M. robiniae, and we have begun partial genomic sequencing of additional cerambycine species to explore the evolution of pheromone-sensitive odorant receptors within the subfamily.

Lost in translation: Modified olfactory inputs drive male moth behavioral responses in interspecific antennal transplants

Seong-Gyu Lee[1], Kathy R. Poole[2], Charles E. Linn[3], Neil J. Vickers[4]

[1]University of Utah, U.S.A., [2]Cornell University, U.S.A., [3]Cornell University, U.S.A., [4]University of Utah, U.S.A.

Insects rely on their olfactory system to locate food sources, enemies, mates, and oviposition sites. Sex pheromone communication is especially critical for successful reproduction in many insect species. To discriminate the pheromone of potential mates against an environmentally noisy background, precise detection and discrimination of sex pheromone composition by the brain is required. In this study, we modified olfactory inputs to the brain by transplanting antennal imaginal discs between two closely-related species of heliothine moth Heliothis virescens and Heliothis subflexa. Behavioral assays showed that the adult transplant males were still attracted to certain combinations of sex pheromone components but the composition of these blends were not typical of those attractive to normal males of either species. We also examined the physiological and morphological characteristics of peripheral olfactory receptor neurons located on the antenna and second-order olfactory projection neurons in the antennal lobe. The results shed light on how the brain assembles an odor "entity" from discrete odorant-specific inputs. Supported by NSF-IOS 0641014 to NJV and CEL

The overexpression of acetylcholinesterase compensates for the reduced catalytic activity caused by resistance-conferring mutations in *Tetranychus urticae*

Deok Ho Kwon[1], Jae Young Choi[2], Yeon Ho Je[3], Si Hyeock Lee[4]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Seoul National University, Republic of Korea, [4]Seoul National University, Republic of Korea

The mutations (G228S, A391T and F439W) and duplication of the acetylcholinesterase (AChE) gene (Tuace) are involved in monocrotophos resistance in the two-spotted spider mites, Tetranychus urticae. The overexpression of T. urticae AChE (TuAChE) as a result of Tuace duplication was confirmed in several field-collected populations by Western blotting using an AChE-specific antibody. To investigate the effects of each mutation on the insensitivity and fitness cost of AChE, eight variants of TuAChE were expressed in vitro using the baculovirus expression system. Kinetic analysis revealed that the G228S and F439W mutations confer approximately 26-fold and 99-fold increases in the insensitivity to monocrotophos, respectively, whereas the insensitivity increased over 1165-fold in the AChE with double mutations. To simulate the catalytic activity of the overexpressed TuAChE in two T. urticae strains (approximately 6 copies for AD strain vs. 2 copies for PyriF strain), appropriate TuAChE variants were combined to make up the desired AChE copies and mutation frequencies, and their enzyme kinetics were determined. The reconstituted 6-copy and 2-copy TuAChEs exhibited catalytic efficiency levels comparable to those of a single-copy wildtype TuAChE, suggesting that, if mutations are present, multiple copies of AChE are required to restore a normal level of catalytic activity in the monocrotophos-resistant mites. In summary, the present study provides clear evidence that Tuace duplication resulted in the proportional overexpression of AChE, which was necessary to compensate for the reduced catalytic activity of AChE caused by mutations.

A novel mechanism of ecdysone biosynthesis regulation in the prothoracic glands of *Bombyx mori*

Masatoshi Iga[1], Takayoshi Nakaoka[2], Yutaka Suzuki[3], Hiroshi Kataoka[4]

[1]University of Tokyo, Japan, [2]University of Tokyo, Japan, [3]University of Tokyo, Japan, [4]University of Tokyo, Japan

In insect, growth and development are controlled and coordinated by the precisely timed changes of the insect steroid hormone, ecdysone. The ecdysone is predominantly synthesized in the prothoracic glands (PGs) and the biosynthesis is intricately regulated by neuropeptides. However, the whole regulatory mechanisms of ecdysone biosynthesis are not fully understood. To elucidate the entire pathway of ecdysone biosynthesis including its regulatory mechanisms, we performed a transcriptome analysis of the PGs in Bombyx mori using next-generation sequencing (NGS). After the NGS, we further screened the candidates by tissue distribution and expression profile of the genes in B. mori. By these screening, we found a G-protein coupled receptor (GPCR) that is strongly suggested to participate in the regulation of ecdysone biosynthesis. The GPCR gene was predominantly expressed in the ecdysteroidgenic tissues, and the expression pattern in the PGs was in concert with the ecdysteroid titer in the hemolymph. Furthermore, we tested the binding of ligand candidates to the GPCR using a heterologous expression system, and found a ligand. The ligand stimulated the ecdysone biosynthesis in the PGs, but not affected to the gene expression of known ecdysone biosynthesis-related enzymes. In addition, the RNAi phenotype of homologous genes of the GPCR in Drosophila melanogaster showed larval lethal or growth delay. These results suggest the importance of this GPCR mediated novel regulatory mechanism in the ecdysone biosynthesis. [This study was supported by the grant from Programme for Promotion of Basic and Applied Researches for Innovations in Bio-oriented Industry.]

A Chitin Deacetylase-Like protein homologue in the spruce budworm, *Choristoneura fumiferana*

Guoxing Quan[1], Tim Ladd[2], Fayun Wen[3], Peter J Krell[4], Basil M. Arif[5]

[1]Great Lakes Forestry Centre, Natural Resources Canada, Canada, [2]Great Lakes Forestry Centre, Natural Resources Canada, Canada, [3]Great Lakes Forestry Centre, Natural Resources Canada, Canada, [4]University of Guelph, Canada, [5]Great Lakes Forestry Centre, Natural Resources Canada, Canada

Chitin is a naturally occurring polysaccharide that is one of the main components of insect exoskeletons and peritrophic membrane (PM), foregut and hindgut, as well as tracheal tissue. It plays a critical role in modelling tissues of various shapes, sizes and mechanical properties. Chitin deacetylase-like proteins (CDAs) convert chitin into its deacetylated form, chitosan, a natural glucosamine polymer. CDAs are members of a family of carbohydrate esterases and have been well characterized in pathogenic fungi and bacteria. Recently, insect CDAs have been isolated and characterized from cabbage looper, drosophila and red flour beetle. Insect CDAs were classified into five ortholog groups based on phylogenetic analysis and the presence of additional motifs. Red flour beetle has five ortholog groups. Group I contains two genes. During knock-down of all the nine CDAs individually, only group I CDA knock down exhibited similar lethal phenotypes and developmental blocks in the red flour beetle. A CDA-like gene was isolated during yeast two hybrid screening using the spruce budworm gene CfRACK1 (Receptor of Activated C Kinase 1) as bait. The deduced amino acid sequence, gene structure and expression profile indicated that the cloned gene from spruce budworm is similar to that in group I CDA in red flour beetle. Its biological roles and potential use in pest control are discussed. This research was supported by grants from the Canadian Regulatory System for Biotechnology (CRSB) and the Genomics R&D Initiative (GRDI).

Structural insight into the funtional and inhibitiory specificity of an insect chitinolytic β-N-acetyl-D-hexosaminidase, a potential pesticide target

Tian Liu[1], Qing Yang[2]

[1]*Dalian University of Technology, China,* [2]*Dalian University of Technology, China*

Chitinolytic β-N-acetyl-D-hexosaminidase (Hex) is a branch of GH20 Hex that is only distributed in insects and microorganisms, and is therefore a potential target for the action of pesticides. OfHex1 from the Asian corn borer, Ostrinia furnacalis, functions merely in chitin degradation. In this study, the crystal structures of OfHex1 was determined. The structural basis for the functional specificity of OfHex1 was attributed to the existence of three conserved residues (Val327, Glu328 and Trp490) at the entrance of the active pocket. To guide the design of pesticide against OfHex1, a selective inhibitor (TMG-chitotriomycin) and a broad-spectrum inhibitor (PUGNAc) were co-crystallized with OfHex1 respectively. TMG-chitotriomycin is a natural selective inhibitor against bacterial and insect Hexs. The selective inhibition of OfHex1 by TMG-chitotriomycin was related to the existence of the +1 subsite at the active pocket and a key residue, Trp490, at this site. Mutation of Trp490 to Ala led to a 2,277-fold decrease in sensitivity toward TMG-chitotriomycin. The sensitivities of chitinolytic Hexs towards PUGNAc can vary in 100 folds [OfHex1 (insect)< SmCHB (bacterium)< SpHex (actinomycete)]. The sensitivities of these enzymes to PUGNAc was dedicated by the active pocket size, with OfHex1 having the largest but with the narrowest entrance, while SpHex having the smallest, suitable for holding the inhibitor, whereas that of SmCHB having the widest entrance. By widening the size of the active pocket entrance of OfHex1 through replacing active site Val327 with Gly, sensitivity of OfHex1 to PUGNAc became similar to that of SmCHB.

A novel alternative splicing site of class A chitin synthase from the insect *Ostrinia furnacalis*

Mingbo Qu[1], Qing Yang[2]

[1]*Dalian University of Technology, China,* [2]*Dalian University of Technology, China*

Insect chitin synthase A (CHSA) catalyzes chitin biosynthesis in tissues that develop from ectoderm. Since only one gene copy encodes CHSA, we hypothesized that CHSA is very likely to exist as isoforms through alternative splicing, and the functions of these isoforms may be tissue-specific. Besides the known alternative splicing exons in the mid-ORF region, we report here the alternative exons (OfCHSA-2a andOfCHSA-2b) of OfCHSA, the chitin synthase A from the lepidopteran pest Ostrinia furnacalis. Sequence analysis of the 50 upstream region of the transcription start site indicated that presences of two independent promoters for controlling the expression of OfCHSA-2a/b. Both OfCHSA-2a and OfCHSA-2b transcripts were preferentially expressed in the epidermis. During growth and development of O. furnacalis, OfCHSA-2a was mainly expressed during larvalelarval molting and larval-pupal transformation, as well as in newly-laid eggs, while OfCHSA-2b was expressed only during the larval-larval molting. Gene silencing of OfCHSA-2a caused incomplete molting, while silencing of OfCHSA-2b exclusively influenced the head cuticle formation of the 3rd instar larval. Since O. furnacalis is phylogenetically close to the model insect Bombyx mori, the same undiscovered alternative splicing exon was also identified in BmCHSA by gDNA sequence alignment. This work may lead to greater understanding of the mechanism by which a single copy of the CHSA gene could fulfill various functions with tissue specificity.

Molecular cloning of chitinase cDNAs from the spittlebug *Poophilus costalis* (Hemiptera: Cercopoidea: Aphrophoridae)

Shu-Chen Chang[1], Hsien-Tzung Shih[2], Kuang-Hui Lu[3]

[1]Taiwan Agricultural Research Institute, Taiwan, [2]Taiwan Agricultural Research Institute, Taiwan, [3]National Chung Hsing University, Taiwan

The spittlebug nymphs feed on plant sap and produce forth to cover their fragile bodies. In this study, we have confirmed the fungicidal effect of the froth of the spittlebug Poophilus costalis by bioassay on the pea wilt pathogen, Fusarium oxysporum f. sp. pisi; in addition, the activities of β-N-actylglucosaminidase, chitobiosidase and endochitinase were observed in the froth. Furthermore, a chitinase cDNA, named PCChi, was cloned from the Malpighian tubules of P. costalis nymphs. The PCChi cDNA contains an 1809-nucleotide open reading frame encoding a protein of 603 amino acids with an estimated molecular weight of 68 kDa. The deduced amino acid sequence of PCChi has 58-86% identities to known chitinases in the other species.

Tick ecdysteroidogenesis - Identification of ecdysteroid synthetic tissues from a soft tick

Mari Horigane Ogihara[1], Juri Hikiba[2], Yutaka Suzuki[3], DeMar Taylor[4], Hiroshi Kataoka[5]

[1]University of Tokyo, Japan, [2]University of Tokyo, Japan, [3]University of Tokyo, Japan, [4]University of Tsukuba, Japan, [5]University of Tokyo, Japan

As in other arthropods, blood feeding ticks require ecdysteroids for development and egg production. During the nymphal stages, blood feeding (engorgement) is a trigger for ecdysteroidogenesis. On the other hand, females require both blood feeding and mating to release ecdysteroids. This indicates that female tick ecdysteroidogenesis is regulated by nutrition and mating. Although studies on tick ecdysteroidogenesis have been carried out in the past, there is little definitive information on ecdysteroidogenesis in ticks, the synthetic organs and enzymes have not been identified. Therefore, the objective of this study was to identify tick ecdysteroidogenic enzymes and synthetic tissues using the soft tick Ornithodoros moubata. Cloning of ecdysteroidogenic enzymes were performed with next generation sequencing and the results revealed two ecdysteroidogenic enzymes: Spook (OmSpo, CYP307A1) and Shade (OmShd, CYP314A1). Spook functions in the ecdysone synthetic tissues and Shade converts ecdysone into active form 20-hydroxyecdysone (20E). OmSpo expression was observed in the ovary and cuticle of fed females. Interestingly, 5th instar nymphs that molt into females also showed OmSpo expression in the disc of the ovary. These results indicate the ovary and gonadal disc are the ecdysteroidogenic tissues of both immature and mature ticks. OmShd expression was strongly observed in the ovary, midgut and malpigulan tubes, but not in the fat body. Therefore, ticks appear to have the similar ecdysteroidogenic pathway as insects and crustaceans, but the synthetic tissues appear to have a unique evolution.

Molecular mechanism of pupal coloration in the silkworm, *Bombyx mori*

Takashi Kiuchi[1], Takeshi Fujii[2], Seigo Kuwazaki[3], Kimiko Yamamoto[4], Susumu Katsuma[5], Toru Shimada[6]

[1]Graduate School of Agricultural and Life Sciences, The University of Tokyo, Japan, [2]Graduate School of Agricultural and Life Sciences, The University of Tokyo, Japan, [3]Agrigenomics Research Center, National Institute of Agrobiological Sciences, Japan, [4]Agrigenomics Research Center, National Institute of Agrobiological Sciences, Japan, [5]Graduate School of Agricultural and Life Sciences, The University of Tokyo, Japan, [6]Graduate School of Agricultural and Life Sciences, The University of Tokyo, Japan

Insect body colors exhibit extreme diversity, and vary depending on the species and individuals. The body colors greatly contribute to achieve camouflage or mimicry together with other morphological and behavioral traits, thereby strongly associated with natural selection. The formation of insect body color is controlled by not only genetic diversity but also environmental stimuli. The domesticated silkworm, Bombyx mori, is a good model insect for studying pigmentation system because it has many body color mutants and advantages of easily handling. Two pupal color mutants have been obtained in Bombyx mori. One is black pupa (bp) and the other is sooty (so). Both pupal skin colors are abnormally black and affected by temperature during the wandering stage. The responsible gene of the so mutant is ebony cloned by Futahashi et al. (2008), but the bp mutant is still unknown. Positional cloning of the bp mutation indicated that L-aspartic acid decarboxylase (ortholog of the Drosophila black gene), which catalyzes β-alanine synthesis, was a first candidate for the responsible gene. The pupal skin color of the bp mutant was recovered by direct injection of β-alanine from black to normal (brown). GC-MS analysis also showed depletion of β-alanine in pupal skin of the bp mutant. From these results, we speculate that the L-aspartic acid decarboxylase gene is responsible for the bp mutation. Now, we are trying to clarify the molecular mechanism of pupal pigmentation affected by both genes and external temperature using bp and so mutants as a model.

Eicosanoids mediate hemolymph oxidative and antioxidative response in larvae of *Galleria mellonella*

Ender Buyukguzel[1], Pavel Hyrsl[2], Kemal Buyukguzel[3]

[1]Zonguldak Karaelmas University, Turkey, [2]Masaryk University, Czech Republic, [3]Zonguldak Karaelmas University, Turkey

Antioxidant enzymes play a major role in the defense against pro-oxidative effects of xenobiotics and prooxidant plant allelochemicals in insects. We posed the hypothesis that eicosanoids also mediate antioxidant enzymatic defense reactions to pro-oxidant challenge. To test this idea, we reared first-instar larvae of Galleria mellonella (L.) with esculetin (0.001%), dexamethasone (0.001%) and phenidone (0.1%) to seventh-instars. Newly ecdysed seventh-instars were then fed on artificial diet containing 0.05% xanthotoxin (XA) for 2 days. High dietary XA concentrations (0.005 and 0.1%) were associated with increasing MDA and carbonyl content (by 3-fold) and antioxidant enzyme activities, superoxide dismutase (SOD) (by 3-fold) and catalase (CAT) (by 4-fold), and glutathione-dependent enzymes, glutathione S-transferase (GST) (by 15-fold) and glutathione peroxidase (GPx) (by 7-fold). Relative to control, eicosanoid biosynthesis inhibitors (EBIs) esculetin, dexamethasone and phenidone also resulted in impaired MDA content and antioxidant enzyme activities. However, carbonyl content did not differ between control- and EBIs-feeding larvae. This oxidative stress was associated with elicited antioxidative responses by increasing SOD, GST and GPx and decreasing CAT activities in hemolymph. We infer from these findings that eicosanoids mediate insect antioxidant enzymatic responses to dietary pro-oxidants.

Post-feeding diuresis in Rhodnius prolixus: The role of FGLamide-related allatostatins

Meet Zandawala[1], Ian Orchard[2]

[1]University of Toronto Mississauga, Canada, [2]University of Toronto Mississauga, Canada

Allatostatins (ASTs) are insect neuropeptides that were first identified as inhibitors of juvenile hormone biosynthesis by the corpora allata. There are three families of ASTs in insects, defined by their C-terminus conserved regions, one of which is FGLamide. Here we determine, for the first time in a hemipteran, the complete 1013bp cDNA sequence encoding the Rhodnius prolixus FGLa/ASTs (Rhopr-FGLa/ASTs). Reverse-transcriptase PCR demonstrates that the Rhopr-FGLa/AST transcript is highly expressed in the central nervous system (CNS) in unfed fifth-instar R. prolixus, and is reduced in expression in CNS dissected from one day old blood-fed insects. Fluorescent in situ hybridization shows transcript expression in neurons in each ganglion of the CNS, but also in cells located on peripheral nerves. Notably, the transcript is localized in five dorsal unpaired median (DUM) neurons in the mesothoracic ganglionic mass, which produce neurohaemal sites over the abdominal nerves. Pre- and post-feeding analysis of allatostatin-like immunoreactivity shows that the intensity of staining is reduced in DUM neurons, abdominal nerves and the open-type endocrine cells in the anterior midgut at 48 hours post-feeding. Rhopr-FGLa/ASTs dose-dependently inhibit contractions of the anterior midgut and hindgut, and heart-beat frequency. We have also examined their effects on secretion by Malpighian tubules. Rhopr-FGLa/ASTs appear to be released into the haemolymph following feeding and to inhibit the activity of various tissues associated with feeding. Lastly, we have predicted a single receptor for FGLa/ASTs in R. prolixus and phylogenetic analysis classifies it as a type 1 receptor, with two allatostatin receptors present only in Drosophila.

The unexpected divergence of juvenile hormone function in highly eusocial tropical wasps

Hans Kelstrup[1], Klaus Hartfelder[2], Fabio Santos Do Nascimento[3], Lynn Riddiford[4]

[1]Janelia Farm (HHMI) / U. of Washington, U.S.A., [2]Universidade de Sao Paulo, Brazil, [3]Universidade de Sao Paulo, Brazil, [4]Janelia Farm (HHMI), U.S.A.

New World swarm founding wasps (Epiponini) represent a pinnacle of eusocial evolution, comparable to honeybees and ants. Yet almost nothing is known about their physiology. This is in stark contrast to primitively eusocial wasps like Polistes which have been interrogated for decades with particular emphasis on the role of hormones in fights among foundresses where, typically, one female will dominate and become the sole egg layer. In contrast to Polistes, swarm founding wasps by definition lack foundresses and solitary phases, multiple queen nests are normal, and dominance interactions have become ritualized in the form of abdomen-bending. Here, we report the endocrine profiles of juvenile hormone (JH) and the ecdysteroids for two species of swarm founders with caste-totipotent adults: Polybia micans and Synoeca surinama. In normal or status quo nests, JH levels were virtually identical between queens and workers of P. micans. In contrast, S. surinama queens showed significantly higher JH titers than workers. Changes in JH titers in both species were nonetheless associated with the transition from young workers to queens in queenless nests. Additional assays performed for S. surinama in a variety of social contexts revealed that JH titers rise following abdomen-bending. Topical application of either methoprene (a JH mimic) or JH III under various circumstances confirmed that JH does not drive the transition but may have a gonadotropic and queen-signaling function. These results demonstrate that the underlying endocrinology of eusocial wasps is much more diverse and labile than expected. Supported by HHMI, CNPq and FAPESP 10/10027-5

Female-specific wing regression triggered by 20-hydroxyecdysone during pupal-adult transformation in the winter geometrid moth *Nyssiodes lefuarius* (Lepidoptera, Geometridae).

Shuhei Niitsu
Tokyo Metropolitan University, Japan

The winter moth Nyssiodes lefuarius is a univoltine species, and the adults appear at early spring after long pupal "diapause" from summer to winter. They show sexual dimorphism in wing form: Males have functional wings of normal size, whereas females lack wings. I previously found that the wing discs of female pupae in N. lefuarius disappeared due to apoptosis during pupal-adult transformation, while those of males continued to develop fully into adult wings. Using light and electron microscopy, further, it was revealed that wing regression of females is involved not only in apoptotic cell death and phagocytosis, but also accompanied by epithelial cell contraction. In the present investigation, to know whether ecdysteroid is involved in such sex-specific wing regression, I tested in vivo condition the effects of 20-hydroxyecdysone (20E) on pupal diapause termination and wing morphogenesis in both sexes. When 20E of 5.4 μg or more was applied, wing morphogenesis began after 4 days of injection and then wing regression was found in females. In males, by contrast, wing morphogenesis including scale formation was induced. These results suggest that ecdysteroid plays important roles in sex-specific wing regression in this geometrid moth.

Regulatory mechanism of the *Drosophila* insulin-like peptides gene expression

Naoki Okamoto[1], Takashi Nishimura[2]

[1]RIKEN Kobe Institute, Japan, [2]RIKEN Kobe Institute, Japan

Members of the insulin-like peptides have conserved roles in the regulation of growth and metabolism in a wide variety of metazoans. The Drosophila genome encodes seven insulin-like peptide genes, dilp1?7, and the most prominent dilps (dilp2, dilp3 and dilp5) are expressed in brain neurosecretory cells known as insulin-producing cells (IPCs). Although these dilps are expressed in the same cells, the expression of each dilp is regulated independently. Furthermore, the expression of one of the three genes, dilp5 is tightly regulated by nutrient availability. However, the molecular mechanisms that regulate the expression of individual dilps in the IPCs remain largely unknown. Here, we show that Dachshund (Dac), which is a highly conserved nuclear protein, is a critical transcription factor that specifically regulates dilp5 expression. Dac was strongly expressed in IPCs throughout development. dac loss-of-function analyses revealed a severely reduced dilp5 expression level. Dac interacted physically with the Drosophila Pax6 homolog Eyeless (Ey), and these proteins synergistically promoted dilp5 expression. In addition, the mammalian homolog of Dac, Dach1/2, facilitated the promoting action of Pax6 on the expression of insulin in cultured mammalian cells. These observations indicate the conserved role of Dac/Dach in controlling insulin gene expression in conjunction with Ey/Pax6 (Okamoto et al., PNAS 2012). Although we revealed the molecular mechanism of dilp5 expression by two transcription factors Dac and Ey, we still do not know how these proteins involve in the nutrient-dependent regulation. In this presentation, we will also show that the molecular mechanism underlying the nutrient-dependent expression of dilp5.

Molecular characterization and gene expression of juvenile hormone binding protein in the Bamboo Borer, *Omphisa fuscidentalis*

Eak-artit Ritdachyeng[1], Stephen S. Tobe[2], Tippawan Singtripop[3]

[1]Chiang Mai University, Thailand, [2]University of Toronto, Canada, [3]Chiang Mai University, Thailand

In this study, we cloned and sequenced the Omphisa juvenile hormone binding protein (OfJHBP). The full-length OfJHBP cDNA sequence is comprised of 849 nucleotides with an open reading frame of 726 bp encoding 242 amino acids. The molecular mass of the protein was estimated to be 26.94 kDa. The deduced protein sequence of OfJHBP showed moderate homology with the lepidopteran, Heliothis virescens JHBP (52% amino acid identity) and lower homology with the Bombyx mori JHBP (45%) and the Manduca sexta JHBP (44%). The OfJHBP was expressed mainly in the fat body. OfJHBP transcripts in the fat body was moderately high during 3rd, 4th and 5th instars, then rapidly increased, reaching a peak during early diapause. The expression remained high in mid-diapause, then decreased in late-diapause until the pupal stage. Application of juvenile hormone analog (JHA) methoprene to diapausing larvae stimulated OfJHBP mRNA expression in the fat body from day 2 after hormone application and reached maximum levels on day 10, then declined to low levels in the pupal stage. The changes of OfJHBP mRNA expression level after 20-hydroxyecdysone (20E) injection revealed that 20E also activated OfJHBP mRNA expression level. OfJHBP mRNA levels increased on day 2 and showed a peak of gene expression on day 6, and decreased to low levels during pupation. Thus, both hormones exhibited a similar stimulatory pattern in OfJHBP expression.These results should contribute to our understanding of how JHBP and JH regulate the termination of larval diapause in the bamboo borer.

Understanding physiological roles of crustacean cardioactive peptide in the blood-gorging bug, *Rhodnius prolixus*

Dohee Lee[1], Angela B. Lange[2]

[1]*University of Toronto at Mississauga, Canada,* [2]*University of Toronto at Mississauga, Canada*

Crustacean cardioactive peptide (CCAP), a cyclic nonapeptide (PFCNAFTGCamide), has multifunctional roles in insects including the stimulation of visceral and cardiac muscle contraction, and the regulation of ecdysis. We have cloned the cDNA sequence of the CCAP gene from Rhodnius prolixus central nervous system (CNS), and shown its expression in the CNS using in situ hybridization. The amino acid sequence of CCAP in R. prolixus CNS was verified by matrix-assisted laser desorption/ionisation (MALDI) time-of-flight (TOF) mass spectrometry (MS) and MALDI-TOF MS/MS. The distribution of CCAP containing neurons and their processes was also shown using immunohistochemistry. In addition, we have sequenced the cDNA of the RhoprCCAP G-protein coupled receptor (GPCR) and examined its expression in the CNS as well as peripheral tissues of R. prolixus. Quantitative real-time reverse transcriptase PCR (qRT-PCR) analysis showed specific developmental expression of CCAP and its receptor in the CNS and peripheral tissues of 4th and 5th instar R. prolixus. Physiologically, CCAP dose-dependently stimulates R. prolixus hindgut contractions, with threshold at 5x10-9 M and maximum response at10-7M CCAP. Also, CCAP increases heartbeat frequency in a reversible, dose-dependent manner, with threshold close to 10-11M and maximum response at 10-10M CCAP. The functional roles of CCAP in ecdysis in vivo are currently being investigated by injecting double stranded RNA (dsRNA) generated by using CCAP and its receptor as templates.

Abstract Title: Kruppel homolog 1 (Kr-h1) plays a key role in the repression of metamorphosis in insects. Kr-h1 is assumed to be induced by Juvenile hormone (JH) via a JH receptor, Methoprene-tolerant (Met), but the mechanism of induction is largely unknown. To gain insights into the molecular mechanism of Kr-h1 induction, we first cloned cDNAs encoding Kr-h1 (BmKr-h1) and Met homologs (BmMet1 and BmMet2) from Bombyx mori. In a B. mori cell line, BmKr-h1 was rapidly induced by subnanomolar levels of natural JHs. A novel JH response element (kJHRE), comprising 141 nucleotides, was discovered at 2 kb upstream from the transcription start site of BmKr-h1 by reporter assays in the B. mori cells. The core region of kJHRE (kJHREc; GGCCTCCACGTG) contained a canonical E-box sequence, to which the Met, a bHLH transcription factor, is likely to bind. In mammalian HEK293 cells, which lack an intrinsic JH receptor, ectopic expression of BmMet2 fused with Gal4DBD induced JH-dependent activity of a UAS-reporter. Meanwhile, the kJHRE-reporter was activated JH-dependently in HEK293 cells when co-transfected with BmMet2 and BmSRC, a steroid receptor coactivater, suggesting that BmMet2 and BmSRC jointly interact with kJHRE. We also showed that BmMet2 JH-dependently interacted with BmSRC. Based on these results, we suggest the mechanism of JH-mediated induction of BmKr-h1 as follows: BmMet2 accepts JH as a ligand, JH-liganded BmMet2 interacts with BmSRC, and JH/BmMet2/BmSRC complex activates BmKr-h1 gene via an interaction with kJHRE.

Insulin signaling is involved in nutritional stress response in pea aphids, *Acyrthosiphum pisim*

Meng Zhang[1], Shan-shan Guo[2], Tong-xian Liu[3]

[1]Northwest A & F University, China, [2]Northwest A & F University, China, [3]Northwest A & F University, China

Researchers have identified the insulin/IGF-like (IIS) signaling pathway as the major signaling pathway coordinating growth and regulating nutritional plasticity in diverse organisms. Less well understood at the molecular level is how organisms adjust their nutritional metabolism in response to the environmental stress. The publication of draft sequence of the pea aphid, Acyrthosiphum pisim, laid a foundation for revealing the relationship between IIS pathway and nutritional assignment under nutrition-related adversity; in particular for winged morphs that are closely with migration. Like hymenopterans, two insulin receptor genes are present in the pea aphid genome, but there are no any experimental data about them in aphids. To elucidate the role of the IIS pathway in pea aphid, two putative insulin receptor genes (AInR-1 and AInR-2) were choose for analysis of gene expression profiles under nutritional deficiency stress. We show that IIS pathway is associated nutritional stress response. Not only winged and wingless adults differ in the level of insulin receptor genes expression when coping with negative nutritional condition, but the scale of expressional changes of two receptors genes is different. These data indicate that IIS pathway presents different modulatory patterns according to tasks that wing dimorphism gives diverse morphs under adverse nutritional condition. And in the progress, the relationships between both insulin receptors may be coordination, but probably one plays a leading role among them.

Queen pheromone regulates egg production in a termite

Yuuka Yamamoto[1], Kenji Matsuura[2]

[1]Okayama University and Kyoto University, Japan, [2]Kyoto University, Japan

In social insects, resource allocation is a key factor that influences colony survival and growth. Optimal allocation to queens and brood is essential for maximum colony productivity, requiring colony members to have information on the total reproductive power in colonies. However, the mechanisms regulating egg production relative to the current labour force for brood care remain poorly known. Recently, a volatile chemical was identified as a termite queen pheromone that inhibits the differentiation of new neotenic reproductives (secondary reproductives developed from nymphs or workers) in Reticulitermes speratus. The same volatile chemical is also emitted by eggs. This queen pheromone would therefore be expected to act as an honest message of the reproductive power of queens. In this study, we examined how the queen pheromone influences the reproductive rate of queens in R. speratus. We compared the number of eggs produced by each queen between groups with and without exposure to artificial queen pheromone. Exposure to the pheromone resulted in a significant decrease in egg production in both single-queen and multiple-queen groups. This is the first report supporting the role of queen pheromones as a signal regulating colony-level egg production using synthetically-derived compounds in a termite.

Analysis of an Innate behavioral sequence by genetic manipulation of a peptidergic signaling cascade

Do Hyoung Kim[1], Mi-Ran Han[2], Young-Joon Kim[3], Michael E. Adams[4]

[1]UC Riverside, U.S.A., [2]cGwangju Institute of Science and Technology, Republic of Korea, [3]Gwangju Institute of Science and Technology, Republic of Korea, [4]UC Riverside, U.S.A.

Insect ecdysis is an example of innate behavioral sequences performed as a fixed action pattern. The release of ecdysis-triggering-hormone (ETH) from endocrine Inka cells drives the stereotypical sequence of ecdysis-related behaviors through direct and sequential activation of peptidergic ETH receptor ensembles in the central nervous system (CNS). Here we show that targeted inactivation and ablation of ETH receptor (ETHR) neurons, including those that express kinin, crustacean cardioactive peptide (CCAP), Allatostatin-CC (Ast-CC), myoinhibitory peptide (MIP), burs, and bursicon (burs and pburs) alter scheduling of the ecdysis sequence. The results demonstrate that kinin is involved in scheduling of pre-ecdysis and that bursicon neurons are necessary for termination of pre-ecdysis and the onset of ecdysis. Concurrent monitoring of neuronal activity by calcium imaging in kinin and bursicon neurons provides compelling evidence for sequential activation of ETH receptor neurons and functional roles of these neurons in ecdysis. Evidence supporting this model is provided through over-expression or silencing of ETHR in kinin and bursicon neurons, and by observations of changes in behavioral scheduling that result from these manipulations. Changes in onset timing of bursicon neurons by over-expression or silencing ETHR were confirmed by calcium imaging. To explain the sequential activation of ETHR neurons, a differential sensitivity model is proposed: variable sensitivity to ETH causes differences in activation timing of ETHR ensembles. Our findings provide new evidence for functional roles of peptidergic ETHR neurons and mechanisms of sequential activation of peptidergic ensembles to schedule steps of the stereotypic ecdysis behavioral sequence.

Osmoregulation in the desert locust *Schistocerca gregaria*, the role of ion transport peptide.

Neil Audsley[1], David Schooley[2]

[1]Fera, United Kingdom, [2]Univeristy of Nevada, U.S.A.

Ionic and osmotic regulation in most insects is ultimately achieved through the selective and controlled reabsorption of solutes and water in the hindgut (ileum and rectum) from fluid secreted by Malpighian tubules. In locusts, the control of Malpighian tubule fluid secretion by diuretic hormones is well established, far less is known of the regulation of reabsorptive processes in the hindgut. Ion transport peptide (ITP), a member of the crustacean hyperglycaemic hormone family, stimulates the uptake of ions (chloride, potassium and sodium), with a concomitant movement of fluid, across the locust ileum in vitro. These processes are mimicked by endogenous cyclic AMP, suggesting that signal transduction is via this second messenger. Acid secretion in the ileum is inhibited by ITP, but not cyclic AMP, implying the involvement of a second receptor and signal transduction pathway. The latter may be via cyclic GMP because this cyclic nucleotide also stimulates ion transport across the ileum, though its effects on acid secretion have yet to be investigated. The involvement of these second messengers in the ITP response will be discussed. Ion and fluid reabsorption across the locust rectum are also stimulated by cyclic AMP and chloride transport stimulating hormone, a peptide partially purified from locust corpora cardiaca. In contrast, ITP has little effect on the rectum, and its physical properties differ to those of CTSH, suggesting reabsorptive processes in the ileum and rectum are differentially regulated.

Orcokinins are conserved peptides in innervation of the salivary gland and rectal sac of ixodid ticks

Ladislav Roller[1], Ladislav Simo[2], Akira Mizoguchi[3], Yoshiaki Tanaka[4], Mirko Slovak[5], Yoonseong Park[6], Dusan Zitnan[7]

[1]Institute of Zoology, Slovak Academy of Sciences, Slovakia, [2]Kansas State University, U.S.A., [3]Graduate School of Science, Nagoya University, Japan, [4]National Institute of Agrobiological Science, Japan, [5]Institute of Zoology, Slovak Academy of Sciences, Slovakia, [6]Kansas State University, U.S.A., [7]Institute of Zoology, Slovak Academy of Sciences, Slovakia

Orcokinins (ORC) belong to a family of neuropeptides conserved within Arthropoda, but their cellular distribution and functions in insects and arachnids are inadequately studied. We employed an antibody against conserved N-reminus of ORC (NFDEIDR) and/or in situ hybridization to analyze cells producing ORC-like substances in various insects (Orthoptera, Hymenoptera, Lepidoptera, Diptera) and in the hard ticks (Acarina: Ixodidae). ORC are distributed in specific neurosecretory cells and interneurons throughout the central nervous system in all studied arthropods. In the ticks (Amblyomma variegatum, Dermacentor reticulatus, Hyalomma anatolicum, Ixodes scapularis, I.ricinus, Rhipicephalus appendiculatus) antibody against ORC labeled two pairs of prominent opisthosomal neurons (SG neurons) that innervate both, the salivary glands and the hindgut. ORC immunoreactive axon terminals exclusively reach only type II salivary aciny and form dense network on the surface of the rectal sac. Intensity of immunoreactivity in the SG neurons axon terminals decreased in the course of feeding in female ticks. Mature forms of orcokinins were detected in synganglia from an unfed I. scapularis female by matrix-assisted laser desorption/ionization-time of flight (MALDI TOF/TOF). Our data indicate that orcokinins may control activity of salivary glands and rectal sac from the synganglion. This study was supported by the Research & Development Operational Program funded by the ERDF (ITMS: 26240220044).

Comparative proteomical analyses of *Anticarsia gemmatalis* and *Spodoptera frugiperda* midguts

Fariba Mehrkhou[1], Mahmoud Ghasemi Kochameshgi[2], Octavio Luiz Franco[3]
[1]*Iran,* [2]*Iran,* [3]*Brazil*

Anticarsia gemmatalis and Spodoptera frugiperda (Lepidoptera: Noctuidae) are serious defoliator of soybean in all word. In order to better understand the digestion process of such pests, this report shows the evaluation of midgut proteins from A. gemmatalis and S. frugiperda by proteomic analyses combining 2D gels and mass spectrometry. Midguts were removed from larvae and total proteins (approximately 650 µg) were extracted and further submitted to 2-DE. Two-dimensional gels from S. frugiperda and Anticarsia gemmatalis analyzed 206 and 385 spots, respectively. Proteins were identified by MS/MS including catalase, enolase, glyceraldehyde-3-phosphate dehydrogenase, arginine kinase, pyrophosphatase and farnesoic acid O-methyl transferase. All proteins identified seem to affect insect development in different ways, being directly involved in their growth or used as an intermediate in metabolic pathways thatmay influence pest development. According our knowledge, this is the first work using two-dimensional electrophoresis associated to mass spectrometry analyses that evaluates the midgut protein expression of both insect-pests. The identification of those proteins could contribute to the understanding of pest physiology leading to the development of novel strategies for pest management. Key words: Anticarsia gemmatalis, Spodoptera frugiperda, Proteomics, Mass spectrometery.

JH acid methyl transferase genomics and its relevance as insect biopesticidal agent

Muraleedharan Damodaran[1], Sinto MS[2], Raji PT[3], Omkumar RV[4], Govindan Bhaskaran[5]

[1]University of Kerala, India, India, [2]University of Kerala, India, [3]University of Kerala, INDIA, India, [4]Rajiv Gandhi Centre for Biotechnology (RGCB) Trivandrum, India, [5]University of Kerala, India

Corpus allatum (CA) the insect endocrine gland that synthesize juvenile hormone (JH), the sesquiterpenoid is the insect morphogenetic hormone that determines the kind of moult that any of the developing insect has to undergo during its developmental process. The enzyme JH acid methyl transferase (JHAMT) being the rate limiting enzyme in the JH biosynthesis process which in turn obviously determines the circulating JH hormone titer at any specific developmental stage hence obviously becomes a critical factor in the processes of development and morphogenesis. Hence targeting JHAMT enzyme in devising endocrine based biopesticides becomes logical and rewarding. Insect JHAMT gene has been cloned and characterized only in a few insect species. We have made a partially successful attempt on these lines mainly focusing to characterize, clone and sequence the insect JHAMT gene family from two different insect species as the silkworm B. mori (Bivoltine CSR2 X CSR4 hybrid strain) and the Mormon butterfly, Papilio polytes in the absence of its available detailed information. Partial sequence (600bp) of P. polytes JHAMT gene on BLAST analysis showed more affinity in sequence similarity towards that of B. mori even contrary to other known sequence data of related papilio species and even multiple sequence alignment using ClustalW showed that the partial JHAMT sequence from P. polytes is exactly similar to that of B. mori JHAMT gene sequence published in the NCBI data base by Shinoda (2003) even though no difference noticed at 762 and 864 position as found in B.mori bivoltine CSR2 X CSR4. Baseline study on diversity, ecology and spatial characterization of invertebrates in and around Lake Tana Sub-basin, Northwestern Ethiopia

Emiru Seyoum Yeshanew
Addis Ababa University, Ethiopia

A baseline study was conducted in and around Lake Tana sub-basin, Northwestern Ethiopia to assess the current status of invertebrates involving the relevant stakeholders in biodiversity conservation. The study focused on the role of invertebrates as components in trophic levels, as indicators of climate change, in minimizing pollution and contribution in sustainable ecosystems management. The baseline study covered 4 aquatic, 4 riparian, 3 wetlands and 4 terrestrial sampling sites, respectively in and around the sub-basin. Accordingly, 16 insect and 6 non-insect orders and 103 insect families and 11 non-insect families were collected, identified and preserved, respectively. The total specimens collected and identified by sampling site included, 585 Aquatic and riparian, 1193 wetlands and 550 terrestrial ecosystems making the over all total of specimens collected, identified and preserved 2328, respectively. The results of the study have shown that the degree of organic pollution due to improper and unlimited release of effluents from nearby Hospitals and hotels combined with that from the municipality poor drainage systems are of concerns. The presentation will focus on attributes of invertebrates as natural resources and on ways invertebrates could be best used as indicators of conditions in various ecosystems. The presentation will flash light on the significance of invertebrates in enhancing biodiversity visa-a-vis food security and livelihoods against the back up of climate change and variability

Biodiversity of stream insects in the Malaysian Peninsula: Spatial patterns and environmental constraints

Salman Abdo Al-Shami[1], Che Salmah MD Rawi[2], Abu Hassan Ahmad[3], Madziatul Rosmahanie Madrus[4]

[1]Universiti Sains Malaysia, Malaysia, [2]Universiti Sains Malaysia, Malaysia, [3]Universiti Sains Malaysia, Malaysia, [4]Universiti Sains Malaysia, Malaysia

The spatial variation in Ephemeroptera, Plecoptera and Trichoptera (EPT) taxonomic composition in headwater forested streams of peninsular Malaysia was studied. The environmental parameters were assessed for their importance to regulate the assemblage composition across the spatial extent of peninsular Malaysia bioregion. The spatial variables were expressed as vectors based on principal coordinates of neighbor matrices (PCNM). The forward selection was based on two stopping criteria to identify the key environmental and spatial variables controlling the EPT taxonomic composition. Eigenvector-based spatial filtering was employed to investigate spatial patterns in the EPT composition, and the variation partitioning technique was applied to estimate the amount of variation in the EPT taxonomic composition attributable solely to environmental and spatial factors. The forward selection retained five parameters (altitude, BOD, velocity, ammonia and DO). These environmental variables explained 13.2% of the total variance in EPT composition. The three spatial variables (PCNM vectors) obtained after forward selection explained 8.4% of composition variation. However, the spatially-structured environmental variables explained 7.5 % of the total variance in assemblage composition of EPT. Altitude was correlated to broad-scale variation and showed to be the most important factor affecting the EPT composition in peninsular Malaysia. Our study revealed spatially-structured patterns of the EPT composition, showing decrease from southern to northern of peninsula Malaysia. The importance of environmental variables in explaining the EPT richness at large spatial scale was highlighted. Our results emphasize the need for spatially-explicit, regional studies to better understand geographical variation of tropical freshwater biodiversity.

Ecological Interactions between non-native and native lady beetles in Maine, the United States

Andrei Alyokhin[1], Christy Leppanen[2]

[1]University of Maine, U.S.A., [2]University of Guam, U.S.A.

Biological invasions are currently one of the primary conservation concerns, rivaled only by habitat destruction by humans. In particular, establishment of exotic lady beetles (Coleoptera: Coccinellidae) may have adverse affects on native lady beetle species. We analyzed changes in coccenillid community inhabiting potato crops (Solanum tuberosum L.) in northern Maine over the past 31 years using records from unsprayed plots maintained at the university research farm. Populations of the two native species, Coccinella transversoguttata Brown and Hippodamia tredecimpunctata (Say) seriously declined following the establishment of exotic species Coccinella septempunctata L., Harmonia axyridis (Pallas), and Propylea quatordecimpunctata (L.). A follow-up survey conducted in different habitats in Maine confirmed that C. transversoguttata and H. tredecimpunctata made up only 0.07% and 1.09% of the total lady beetles collected, respectively. Native species were found in very low numbers in all of the habitats surveyed, and in a higher proportion in agricultural habitats when compared to non-agricultural habitats. In laboratory arenas, H. axyridis was the most successful aphid predator, being able to find aphids more quickly and consume more of them compared to most other lady beetle species. It was also by far the most aggressive of the tested species. H. axyridis was also the most successful forager in the presence of the highly aggressive aphid-tending ants Myrmica rubra L. Furthermore, H. axyridis seemed to be highly tolerant of ant venom.

Winter-flooded rice cultivation promotes biodiversity of aquatic insects. - Comparisons under different cultivation management systems in Shiga, Japan

Kosuke Nakanishi[1], Kota Tawa[2], Baku Kanbara[3], Daisuke Murakami[4], Hiroichi Sawada [5]

[1]The University of Shiga Prefecture, Japan, [2]The University of Shiga Prefecture, Japan, [3]The University of Shiga Prefecture, Japan, [4]The University of Shiga Prefecture, Japan, [5]The University of Shiga Prefecture, Japan

We surveyed aquatic insect communities in paddy fields to examine effects of differences in the cultivation management in Shiga Prefecture, Japan. We set up following four types of paddy fields under different cultivation management systems: conventional management with an application of standard amount of agrochemicals and being kept dry during winter (CV), reduced-agrochemical management and being kept dry during winter (RD), no agrochemical management and being kept dry during winter (OG), and no agrochemical management and being flooded during winter (WF). We selected three orders of aquatic insects: Odonata, Hemiptera, and Coleoptera as targets. In WF paddies aquatic insects were most abundant both in the number of species and individuals throughout the census period. This suggests that winter-flooded managements promoted biodiversity of aquatic insects. In contrast, some species such as Sympetrum was less abundant in WF paddies, indicating their low suitability as the habitats for the nymphs. This is assumed to be due to strong predation pressure, because there were abundant aquatic insects as carnivores in WF paddies. Both in CV and RD paddy fields, aquatic insects were fewer in terms of both the number of species and individuals. This was largely due to the enhanced mortality of the aquatic insects, which was assumed to be killed by agrochemicals used in the early season.

Parasitoid and pollinator networks in an Australian agro-ecosystem

Michelle Louise Yates[1], Nigel Andrew[2], Jane Memmott[3]

[1]University of New England, Australia, [2]University of New England, Australia, [3]Bristol University, United Kingdom

Insect pollinators and aphid-parasitoid wasps provide two very important ecosystem services in agro-ecosystems. We collected insect pollinators and aphid parasitoids in farmed and non-farmed habitats, with the aim of assessing if these services cross-over between habitats. Pollinators were collected via vane traps and hand collections, and pollen was swabbed from their bodies to assess their movements between habitats. Aphids and parasitoids invade crops each growing season, presumably from surrounding vegetation. Preliminary results show that aphid and parasitoid populations fluctuated a great deal within the farmed habitats, between years, whilst their populations were fairly similar between years within the non-farmed habitats. Aphidius ervi was found in large numbers in pea aphids on medicago denticulata in the non-cropped habitat, and it has the potential to control the rose-grain aphid which is the common pest aphid of barley crops. However, we did not find evidence of cross-over between farmed and non-farmed habitats, although there is the potential for this to occur. Apis melifera was the most common insect pollinator in both farmed and non-farmed habitats. It did not appear to discriminate between native and non-native plants. 19 Native bee species were recorded, and one new species was discovered. Pollen swabbing revealed cross-over between farmed and non-farmed habitats.

Cryptic species and putative Mullerian mimicry conceal the role of biogeography in the diversification of Danaus butterflies

David J. Lohman[1], Gabriela F. Farias Quipildor[2]

[1]City College of New York-CUNY, U.S.A., [2]City College of New York-CUNY, U.S.A.

By most accounts, the pantropical butterfly genus Danaus has 5 Australasian, 1 Australasian/African, and 6 New World species, including the migratory Monarch butterfly, D. plexippus. To identify the sister species of the Monarch, we reconstructed the evolutionary history of the genus using ~3,300 bp from four molecular markers sequenced from each of >70 specimens from 11 conventionally accepted species (D. plexaure was unavailable). Results from parsimony, maximum likelihood, and Bayesian methods were strongly supported and largely concordant, revealing that 1) the sister species of the Monarch is not D. erippus as often suggested; 2) D. petilia is genetically distinct from its sister, D. chrysippus; and 3) three Australasian species are polyphyletic as currently circumscribed, requiring taxonomic changes. The geographical distributions of these newly recognized species in the Indo-Australian Archipelago suggest an important role for Wallace's Line and Lydekker's Line as dispersal barriers for these volant insects. Moreover, visual comparisons reveal striking similarity in wing color, pattern, and shape among co-distributed Danaus, suggesting that some species or subspecies may be Mullerian mimics of each other.

Revisiting the ants of Melanesia and the taxon cycle: Historical and human-mediated invasion of a tropical archipelago

Evan Philip Economo[1], Eli Sarnat[2]

[1]*Okinawa Institute of Science and Technology, Japan,* [2]*University of Illinois, U.S.A.*

In synthesizing his work on the Melanesian ant fauna, E. O. Wilson proposed a hypothesis for biodiversity dynamics in space and time- the taxon cycle. For the first time since Wilson's landmark studies, we test predictions of a Melanesian taxon cycle with a new dataset on habitat distributions of the entire Fijian ant fauna (183 spp.), and a phylogenetic analysis of the hyperdiverse genus Pheidole in the Indo-Pacific. We find that after colonization, lineages shift from marginal to interior habitats, from ecological generalism to specialization, and from high to low population density, consistent with a historical taxon cycle. Interestingly, exotics are following a similar pathway to these older natural invasions and now dominate the marginal habitats, which may be the first phase of an incipient global taxon cycle in ants.

Managing riparian margins for biodiversity benefits

Jenni Stockan[1], Glenn Iason[2], John Baird[3], Mark Young[4]

[1]The James Hutton Institute, United Kingdom, [2]The James Hutton Institute, United Kingdom, [3]University of Aberdeen, United Kingdom, [4]University of Aberdeen, United Kingdom

Current restoration of stream and other lotic freshwater systems to 'good ecological status' has focused on the creation of riparian buffer strips. Although primarily established to reduce nutrient and sediment run-off from agricultural land, buffer strips are perceived as having multiple benefits including for biodiversity. This study aimed to assess the effects of buffer strips on biodiversity within three river catchments in north-east Scotland. Carabid beetles and pollinators (bees, butterflies and hoverflies) were chosen as biodiversity indicators. Field observations on forty-one buffer strips revealed that, in the short to medium term, buffering creates a homogenous sward atypical of good quality riparian habitat with few truly riparian species present. Studies on carabid beetle movement demonstrated a correlation between activity and vegetation structure. Finally, an experimental approach suggested that cropping or low-intensity grazing offer more sustainable methods of managing these margins. Failure to improve these riparian habitats by buffering alone is because intensive agricultural landscapes do not have sufficient diversity of habitats nor diversity of structure within habitats, to allow colonisation and persistence of a wider suite of species to be promoted. Furthermore, buffering has not addressed the broken linkages between the riparian hinterland, the river banks and the natural flow regime. Restoration of riparian margins is likely to require a range of measures at a catchment scale and over a longer timeframe.

Roles of Insects in the Mesozoic Ecosystems of Northeastern China

Shu Li[1], Dong Ren[2], Hong Pang[3]
[1]Sun Yat-sen University, China, [2]Capital Normal University, China, [3]Sun Yat-sen University, China

Insects have been in existence for at least 400 million years. These relatively small-sized terrestrial arthropods, equipped with their durable cuticle, allowed them to be preserved in compression fossils and ambers. Based on insect fossils collected in northeastern China (i.e. Liaoning, Inner Mongolia and Hebei), at least 19 orders and more than 300 species have been reported (Ren et al. 2010, 2012). Fossil findings and associated studies in China have made significant progress and contribution to Paleoentomology in recent years. Many insects have close interactions with plants, as demonstrated in many Mid-Mesozoic cases. Protonemestrius jurassicus, a dipteran, had a long tubular mouthpart, suggesting its feeding of sugary fluids, which is important for the study of the origin of angiosperms (Ren, 1998). A probable pollination mode before angiosperms was proposed based on three clades of Eurasian, long-proboscid fossil mecopterans from the Middle Jurassic to the Early Cretaceous, which fed on ovular secretions of extinct gymnosperms and engaged in pollination mutualisms with gymnosperms (Ren et al. 2009). Two extraordinary fossil lacewings (Neuroptera) demonstrate a pre-angiosperm origin for leaf mimesis, revealing a lost evolutionary scenario of interactions between insects and gymnosperms (Wang et al., 2010). Recently, a Jurassic katydid (Orthoptera) was described, which had the stridulatory files on wings to produce low-pitched musical songs to attract females in the mid-Jurassic forest (Gu et al. 2012). Based on the coexisting plants and other animals, we established a structure of the ecosystems for the Yanliao Biota and Jehol Biota respectively.

Influence of the river regulation works on ground beetle assemblages in riverbeds of the Yodo River flowing through northern Osaka Prefecture, central Japan

Takahiro Fujisawa[1], Minoru Ishii[2]

[1]*Osaka Prefecture University, Japan,* [2]*Osaka Prefecture University, Japan*

Landscapes of the Yodo River have been heavily changed since 1971 by river regulation works such as dam construction and extensive excavating. A field survey of ground beetle assemblages (Carabidae and Brachinidae) using unbaited pitfall trapping was carried out in the riverbed of the Yodo River from April to December, 2009 to elucidate the influence of the works on the assemblages. Ground beetles were captured for a week twice a month at 13 sites, where we measured four environmental parameters, riverbed conditions (minor or major bed), submergence period, soil moisture percentage and median particle diameter, at each sites. As a result, a total of 8,697 individuals of ground beetles belonging to 65 species were captured from the whole sites. According to the DCA analysis, 14 species including Harpalus crates, Oodes vicarius and Pterostichus eschscholtzii were ordered at scores of more than 1.0 on axis 1 with 13 species like Synuchus nitidus, Carabus yaconinus and Lesticus magnus lower than -1.0. Moreover, the results of the GLMM revealed that many of former species were related to minor bed and high frequency of submergence duration, and many of latter species were related to major bed and ground aridification. Thus the ground beetles in the riverbed of the Yodo River could be classified into two groups from the result of DCA, showing influence of aridification and/or stability of the riverbed due to the river regulation works.

Effects of plantation management on scarabs feeding on eucalypt and understory grass host plants.

Adam Frew[1], Markus Riegler[2], Uffe N. Nielsen[3], Scott Nicholas Johnson[4]

[1]University of Western Sydney, Australia, [2]University of Western Sydney, Australia, [3]Univeristy of Western Sydney, Australia, [4]University of Western Sydney, Australia

Management practices can influence insect populations through numerous mechanisms including changes in host plant chemistry and the community dynamics of other plants in the system. Eucalypt plantations account for 90% of the 100 million ha of forest and woodland in Australia and are becoming of considerable commercial importance globally. In a large-scale field experiment, involving 2560 E. saligna trees, we investigated the individual and combined effects of irrigation and fertilisation on scarabs associated with E. saligna. These scarabs typically feed on eucalypt leaves as adults and on the roots of grasses in the understory and adjacent grassland habitats as soil-dwelling larvae. Scarab populations were dominated by Sericesthis nigrolineata (67.5%), Christmas beetles (Anoplognathus porosus) (18.1%) and the Argentine scarab (Cyclocephala signaticollis) (11.31%). We found that irrigation increased adult scarab abundance by 52.3%, increased understory grass cover from 0.47m m-2 to 0.63m m-2 and influenced which grass species were present. There was generally a negative correlation between grass cover and density of larvae in the soil, however some patches with high grass cover contained large numbers of larvae, potentially suggesting preferential oviposition. We suggest that scarab populations were influenced by the effects of irrigation, which determined host plant quality and the nature of plant assemblages generally (e.g. canopy cover, species composition). In complimentary laboratory experiments, we determined whether the dominant scarab, Sericesthis nigrolineata, would change host preferences on the basis of host plant nutritional quality (e.g. primary and secondary compounds) and found that adults readily shift from E. saligna to E. grandis.

Diversity, distribution and plant association of thrips belonging to *Frankliniella* genus in East Africa

Subramanian Sevgan[1], Sandra Kumm[2], Johnson Ounya Nyasani[3], Monicah Waiganjo[4], Samuel Muchemi[5], Gerald Moritz[6]

[1]ICIPE - African Insect Science for Food and Health, Kenya, [2]Martin-Luther-University Halle-Wittenberg, Germany, [3]icipe - African Insect Science for Food and Health, Kenya, [4]Kenya Agricultural Research Institute, Thika, Kenya, [5]Kenya Plant Health Inspectorate Service, Kenya, [6]Martin-Luther-University Halle-Wittenberg, Germany

The genus Frankliniella Karny is the second largest in the family Thripidae with many polyphagous thrips and tospovirus vectors which are Neotropic and Nearctic in origin. The invasive Western Flower Thrips (WFT), Frankliniella occidentalis (Pergande) and F. schultzei Trybom are known to occur in East Africa. However detailed information on the distribution and diversity of Frankliniella sp. is lacking in East Africa. Detailed surveys in over 250 locations were undertaken from August 2008 to July 2010. Both the dark and pale forms of WFT were found restricted to the high and mid altitude regions of Kenya. Frankliniella schultzei, the most widespread species was observed in high-, mid- and low altitude regions of East Africa. Both pale forms with short third ocellar setae (OSIII) and dark forms with long OSIII were observed in East Africa. Molecular analysis of the ITS1/ITS2 sequences of F. schultzei forms with RFLP technique indicated high degree of divergence between them. While WFT and F. schultzei were frequently pest on French beans, tomato and capsicum; the latter was also pest on potato, egg plant, cucurbits, amaranthus, pigeon pea etc. For the first time we observed the occurrence of Frankliniella williamsi Hood 1915 and Frankliniella borinquen Hood, 1942 from East Africa. While F. williamsi was frequently observed on graminaceous plants such as maize, sorghum, rice and wheat, F. borinquen was frequently observed on the weed, Tithonia diversifolia (Hemsl.) A Gray. Further detailed information on the plant-association, distribution will be presented in this paper.

Aquatic insect assemblages in artificial ponds newly created in a Satoyama coppice in southern Osaka, central Japan

Masahiro Suzuki[1], Norio Hirai[2], Minoru Ishii[3]

[1]Osaka Prefecture University, Japan, [2]Osaka Prefecture University, Japan, [3]Osaka Prefecture University, Japan

Many species of aquatic insects are threatened due to degradation of the habitats in Satoyama, the traditional rural landscape in Japan. Recently creating artificial ponds has been made as a practice for their conservation in Japan. In this study, we placed two plastic artificial ponds (134 × 74 cm, 20 cm in depth) each inside (Site A), on the edge (Site B) of, and outside (Site C) a Satoyama coppice in southern Osaka, central Japan, and aquatic insects were counted twice a month from April to December 2011. As a result, a total of 25 species from 16 families were recorded from all the six ponds. Species richness was higher at Site A (17 species) than at Sites B and C (13), while the number of individuals was the largest at Site C (34,374), followed by Site A (19,775), and the smallest at Site B (18,178) . At Site A, Cloeon spp. (Baetidae) were dominant with the rate of occupancy > 86%, while Chironomidae spp. dominated at Sites B (> 50%) and C (> 80%). According to the cluster analyses using similarity indices, two groups of assemblages, those of Site A and Sites B and C, were recognized. Throughout the survey period, the rate of sky view was higher at Site A (47-59%) than at Sites B and C (18-43%). The results show that the structure of the aquatic insect assemblage developing in the artificial pond is strongly affected by the light condition.

Interspecific relationships in grassland ground beetle (Coleoptera: Carabidae) assemblages

Gabor Pozsgai
The James Hutton Institute, United Kingdom

Although interspecific relationships can significantly alter the composition of insect assemblages they are often ignored when assessing impacts of environmental change. Long-term ground beetle data were used in this study to analyse ecological networks at two sites in Scotland. Bayesian Network inference algorithm was used in order to reveal interspecific relationships. 1000 permutations of greedy searches were computed to identify possible networks. Highly probable links between nodes (species) were filtered from the permutations and the strength of each relationship was estimated. Most interspecific relationships were found to be positive. The few negative relationships had low influence scores. Pterostichus strenuus, P.nigrita and Clivina fossor appeared to have the most connections to other species, whilst Synuchus vivalis, Carabus violaceus and P. madidus appeared to be the key species within the assemblage, having strong links to several other species that persisted across replicates. One of the weak negative relationships found in the network was between Loricera pilicornis and Leistus terminatus suggesting existence of competition for their collambolan prey. Despite their high relative abundance Nebria brevicollis and Carabus problematicus did not have numerous strong links to other species. Several species had no or only one link. These species are found in high abundance in areas adjacent to the study site but rarely within the specifically studied habitat, suggesting that they do not play an important role in this particular ecological network. In contrast, species with several strong relationships are likely to be key species thus being of special interest for conservation and land management.

The Argentine ant, *Linepithema humile*, interferes with the foraging success of native ant species in a biodiversity hotspot.

Natasha Palesa Mothapo[1], Caitlyn Joubert[2], Theresa Clair Wossler[3]

[1]Department of Botany and zoology, Stellenbosch University, South Africa, [2]Department of Botany and Zoology, Stellenbosch University, South Africa, [3]Department of Botany and Zoology, Stellenbosch University, South Africa

In the Cape Floristic Region (Fynbos) of South Africa, a biodiversity hotspot characterised by high levels of endemism, Argentine ants displace myrmecochorous native ant species. However, no studies have investigated the mechanisms by which these native species are displaced. We investigated the response of Fynbos native ant species to invasion by Argentine ants by measuring their competitive ability and foraging success under laboratory conditions. Resource exploitation by native ant species and Argentine ants of equal colony sizes were compared. Argentine ants recruited the most number of workers and retrieved significantly more of the bait compared to all native species. We then compared interference and resource exploitation by a colony of native species with that of Argentine ants. During resource competition, Argentine ants did not locate the bait faster than native ants, however, once located, they rapidly displaced native ant species within the first 10 minutes of the trial through high interspecific aggression which contributed to their dominance at the bait. Argentine ants outcompeted native ants from different subfamilies and functional groups, through numerical and behavioural dominance at the bait. Pheidole capensis and Anoplolepis custodiens, thought to limit Argentine ant invasion within the Fynbos, were severely affected by Argentine ants. Their inability to compete with Argentine ants paints a bleak picture for the future of 53% of Proteacea species and 20% of Fynbos plants that depend on ants for seed dispersal. This study shows no support for biotic resistance to Argentine ant invasion in the Fynbos.

Diversity in the genome of *Ephestia cautella* Walker (Lepidoptera: Pyralidae) strains from Southwestern Nigeria

Adegoke Victor Oyedokun[1], Adebayo Amos Omoloye[2], Babasola Daniel Adewale[3], Segun Isaac Oyedeji[4], Feyisara Abiodun Okelana[5]

[1]Cocoa Research Institute of Nigeria, Nigeria, [2]University of Ibadan,Ibadan, Nigeria, Nigeria, [3]Cocoa Research Institute of Nigeria, Nigeria, [4]Bells University of Technology, Ota, Ogun State, Nigeria, [5]Cocoa Research Institute of Nigeria, Nigeria

This study aimed at understanding the diversity of the strains of E. cautella collected from Southwestern Nigeria. Collections of male and female strains of E. cautella were made in 16 different locations in Southwestern Nigeria. Genomic DNA was extracted from each of the sexes and the whole genome profile of each was generated using two specific primers: Mariner Transposase Gene (MTG) and Mariner Transposase Pseudogene (MTP). The primers differed in their probing capacity; while MTG identified an average of 983 total genomic length, MTP identified 977. The average gap within the length was 321.6 and 419.7 for the two primers respectively. The average Gower genetic distance which existed between the 32 strains for each primer were 0.395 and 0.407 respectively. The least (0.228, between Iyin Ekiti Male and Ile- Oluji Male) and the highest (0.476, between Iyin Ekiti Male and Awe Male) Strains genetic distances in this study occurred in Primer 1 and among the male strains. The average genetic distance among the female strains were 0.403 and 0.418 for MTG and MTP respectively. The intra-specific similarity in the studied population is about 60%, genetic variation were more significant among the male than the female strains. While results from this study unraveled the diversity within this species, it could also form a nucleus for understanding the virulence of the different strains and such could equally guide in the development of a good strategy for the control of the pest.

Canola brassica napus is subject to attacked by various invertebrate pest all over the world. At least 30 species of invertebrates' pest have been found feeding on canola plants. However complex of pest species varies with crop growth stages and production area. Aphids are among most destructive pests of canola crop,its occurrence and severity of infestation have been recorded to be inconsistent during different crop seasons.Population studies of insect are one of important part of pest management strategy Studies regarding the determination of species richness of Brevicoryne brassicae, Myzus persicae and Lipaphis erysimi) (Homoptera: Aphididae).) and its associated natural enemies were conducted in different areas of Punjab, Pakistan. The objective of the study was to develop insect pest management strategy by exploring seasonal abundance of aphids at Faisalabad, Bahawalpur and Dera Ghazi Khan and Khanpur areas of Punjab, Pakistan. Top 10 cm inflorescence of six randomly selected plants in each plot was beaten 10 times with a 15 cm long stick of pencil thickness and dislodged aphids species were counted on a white paper sheet held under inflorescence. Sampling for aphid was done weekly. The specie evenness and specie richness was determined by using shanan,s index

Decrease of ant diversity due to forest disturbance

Tae-Sung Kwon[1], Cheol Min Lee[2]

[1]Korea Forest Research Institute, Republic of Korea, [2]Korea Forest Research Institute, Republic of Korea

Ant monitoring had been carried out at the LTER site in the Gwangneung forest in South Korea for 3 years from 2003. Ant diversity was significantly lower in 2004 than in 2003 and 2005. When abundance of ant species was compared among these years, forest species decreased but grassland species increased. This abrupt change was caused by forest disturbance, which was indicated by decrease of leaf area index (LAI) showing the dropping of many branches. Four functional guilds of ants differently responded to this forest disturbance; forest ground forager (FGF) and soil and litter forager (SLF) decreased but grassland ground forager (GGF) and understory vegetation forager (UVF) increased. The species richness was mainly influenced by decrease of SLF, and the species diversity (H') mainly decreased due to a sudden increase of a GGF species, Formica japonica. Through examination on weather data and insect pest, it was supposed that the forest disturbance would be caused by insect outbreak, and/or by heavy rain and/or by typhoon. Based on the present study, a mechanism was supposed for the decrease of ant diversity after the forest disturbance.

Altitudinal pattern of ant diversity in Korea: An empirical test of mid-domain effect and Rapoport's rule, and an alternative suggestion

Tae-Sung Kwon[1], Jung Hwa Chon[2], Cheol Min Lee[3]

[1]Korea Forest Research Institute, Republic of Korea, [2]Korea Forest Research Institute, Republic of Korea, [3]Korea Forest Research Institute, Republic of Korea

The mid-domain effect and the Rapoport' s rescue effect are diversity theories that explain prevalent diversity patterns, including hump-shaped patterns or monotonic decreases along altitude or latitude gradients. We tested whether patterns of ant species richness along altitudes in South Korea can be described by these patterns. Ants on 12 high mountains (> 1,100 m) throughout South Korea (from 33o N to 38o N) were surveyed using pitfall traps at intervals of 200 to 300 m of altitude. Abundance of ant species was significantly related with altitude and temperature. Species richness of ants decreased monotonically along altitudinal and temperature gradients. However, species richness of cold adapted species (highland species) showed a hump-shaped pattern along altitude and temperature gradients. The altitudinal and temperature ranges of ant species follow Rapoport's rule. Because of the limited occurrence of highland species in highlands, the monotonic decrease could not be explained by Rapoport's rescue effect. Based on the temperature-dependent distribution, we devised an integrative diversity hypothesis that explains local diversity patterns (monotonic decrease, hump-shaped, and monotonic increase) and global diversity patterns (peaks in the tropical region and gradually decreases toward the poles). This hypothesis predicts the prevalence of the hump-shaped pattern in warm regions, which is supported by published insect data.

Last half century we've achieved economic success by development and urbanization, but it had been ignored so far that environmental destroying. After entered 21st century, however, now it is growing steadily people's interest on improving 'quality of life' but also living and natural environment. Therefore, The Seoul City Government had accomplished Cheonggyecheon Restoration Project. This unprecedented large scale restoration suggests the possibility of fulfill the harmony between human and natural environment. Especially Cheonggyecheon is now attention as the urban ecology stream, there are many insect communities which have high environmental adaptability exist with the other living organisms. In this study, we focused on those insect's settlement. We've monitored totally 18 times include day and night survey, during 2007 to 2010. The collecting results of each year are as follows: 174 species, 67 families belonging to 11 orders were recorded in the year 2007; 192 species, 70 families belonging to 10 orders were recorded in the year 2008; 206 species, 72 families belonging to 11 orders were recorded in the year 2009; 248 species, 94 families belonging to 12 orders were recorded in the year 2010; total 433 species, 125 families belonging to 13 orders were recorded. Fragmentarily this result showed that biodiversity of insect was continuously increased after restored. The important species for monitoring of Cheonggyecheon as follows: Locusta migratoria (Protected species in Seoul), Lycorma delicatula (Alien insect), Sericinus montela koreanus and Papilio xuthus (Papilionidae).

The mites comprise a large group of Arthropods belonging to subclass Acari of class Arachnida. Mites belonging to the Order Mesostigmata have gained the attention of the scientists being the potential predators of other harmful mites it's belonging to the Parasitiformes. The present study reveals the Mesostigmata species composition of mites in Arignar Anna Zoological Park (AAZP), the study was conducted during April 2011 to March 2011. The samples were collected from the cages of mammals, birds and reptiles and were examined. Mites were extracted using the Berlese method and mounted in Hoyer's medium. We encountered 23 Species belonging to Mesostigmata Orders, Species richness is dominant in Phytoseiidae family with more species abundance in genus Amblyseiinae and Macrocheles.

Diversity and foraging ecology of pollinators in mango (*Mangifera indica*): An Indian perspective

Poluru Venkatarami Reddy[1], Abraham Verghese[2], Varun Rajan[3], Kavitha Bhimesh[4], Rashmi T[5]

[1]Indian Institute of Horticultural Research, Bangalore-560089, India, [2]Indian Institute of Horticultural Research, India, [3]Indian Institute of Horticultural Research, India, [4]Indian Institute of Horticultural Research, India, [5]Indian Institute of Horticultural Research, India

Mango (Mangifera indica L.), is the most important tropical fruit crop of India. As mango is an entomophilous crop, pollinators have a significant role to play in enhancing the productivity. Studies were conducted at Indian Institute of Horticultural Research, Bangalore, India during 2010-12 to document the diversity of insect pollinators and their foraging behavior in relation to climate as well as genotype variability. Pollinator activity during off-season on the existing vegetation in the orchard was also recorded to assess the benefit of conserving fauna during off-season. Four hundred panicles per variety were observed for pollinator density and abundance on fourteen commercially cultivated varieties. Four species viz. Apis florea (Hymenoptera: Apidae), Chrysomya megacephala and Stomorhina discolor (Diptera:Calliphoridae), Eristalinus arvorum (Dipteral: Syrphidae) were the dominant foragers significantly contributing to pollination. There were no significant differences among varieties with respect to species complex but significantly differed in terms of abundance. Indian rock bee, Apis dorsata was actively foraging in the northern part of country, representing sub-tropical climate while it was absent in other regions. Stingless bee, Trigona iridipennis was abundant in the western region characterised by coastal climate. Flowering was the single most important factor influencing the pollinator density followed by maximum temperature and relative humidity. Honey bees and dipterans responded differently to raising temperatures. Pollinators' response to climate variables is discussed which in turn would help in understanding the climate change driven shifts in mango, a highly seasonal pollinator dependent tropical fruit crop.

ABSTRACT The present communication deals with the studies on diversity and distribution of larval Chironomids from Balaghat ranges of Maharashtra India. In present study subfamily Chironominae is described with twenty one species belonging to seven genera. Genera Chirnomus, Cryptochironomus, Cryptotendipes, Dicrotendipes, Glyptotendipes, Kiefferulus and Polypedilum are found in study area. Genus Chironomus and Dicrotendipes showed high diversity with five species each. Genus Polypedilum is described with four species followed by it genus Kiefferulus with three species. Genus Glyptotendipes is reprsented by two species whereas genera Cryptochironomus and Cryptotendipes are reprsented by single species each.

Insects are the most diverse components of ecosystem. Monitoring of insects provide indications of the early warning of the ecological changes. In the present study we have examined the distribution and abundance of insects across the three vegetation areas of Nilgiri Biosphere Reserve. The site I represents grassland and cattle grazing areas, Site II represents the monoculture plantation of eucalyptus and site III as agricultural land. The insect diversity in Nilgiri Biosphere Reserve was investigated using pitfall trap, hand picking method, sticky glove methods, and yellow pan trapping methods from April 2010 to August 2010 which resulted in 11 orders of insects namely Lepidoptera, Odonata, Hymenoptera, Hemiptera, orthoptera, Diptera, Phasmida, Coleoptera, Dictyoptera, Isoptera, Dermaptera and 2,692 insects belonging to different orders were recorded. The diversity was calculated by using Shannon Wiener Index, resulted 2.37, 2.30, and 2.36 in site I, II and III, respectively. During the study period we recorded less abundance of insects in monoculture plantation due to the influence of human activities in the form of solid waste dumping than other sites. The insect abundance belonging to Diptera (140) and Dictyoptera (108) were dominant which adapted to Monoculture plantations. So, the present research observed the fluctuations in insect population among the sites.

The Pavo cristatus is Indian Peacock or Blue Peacock, called (common Peafowl) belongs to the Kingdom Animalia. It is now reported to be discontinuously distributed in its former distribution range. The present study focuses on the diversity and behavior of Pavo cristatus in Bharathair university campus and VOC park. Direct method and indirect method were carried out for the survey in selected sites. The distribution of peafowl diversity was recorded based on the survey and the same has been calculated using Shannon wiener index. The present study reveals that the diversity of peafowl's is more in domesticated than wild and captive habitat, and in domesticated the diversity of Peahen shows much abundance than Peacock. We determine the behavior of the peafowl's also shows higher variation in domesticated habitat shows the habitat is well utilized by the peafowl's inside the university campus. Compared to wild and captive the death rate and disease attack is less in domesticated habitat.

Effects of temperature stress on tropical insects: A case study with the brown planthopper *Nilaparvata lugens* (Stal)

Jiranan Piyaphongkul[1], Jeremy Pritchard[2], Jeffrey Bale[3]

[1]University of Birmingham, United Kingdom, [2]University of Birmingham, United Kingdom, [3]University of Birmingham, United Kingdom

Nilaparvata lugens (Stal) is the most serious rice pest and widely distributed across Asia. Experiments were carried out to determine the effects of heat stress on nymphs and adults of N. lugens by measuring critical thermal maximum (CTmax), heat coma temperature (HCT) and upper lethal temperature (ULT50). Further experiments investigated the ability of the insect to acclimate at low (15°C) and high temperatures (30oC) compared with the standard rearing regime (23°) by determining critical thermal minimum (CTmin), CTmax, chill coma temperature (CCT), HCT, lower lethal temperature (LLT50) and ULT50. Nilaparvata lugens also showed changes in their thermal tolerance after acclimation. When the rearing temperature was decreased from 23 to 15oC the LLT50 decreased from 2.3±0.4 to 0.5 ±0.4°C in nymphs and from 0.9±0.5 to -2.7±0.4°C for adults. The CTmin was similarly decreased from 15.3±0.3 to 12.5±0.3, 13.1±0.4 to 8.1±0.2 and 12.9±0.4 to 8.8±0.2°C; and the CCT from 6.7±0.2 to 6.2±0.2, 2.1±0.2 to -1.2±0.3 and 2.6±0.2 to -0.3±0.2°C for nymphs and adult females and males. With high temperature acclimation at 30°C the ULT50 increased from 41.8±0.1 to 42.9±0.1 and 42.5±0.1 to 43.6±0.1°C for nymphs and adults, the CTmax from 34.9±1.3 to 37.2±0.1, 37.0±1.0 to 37.3±0.1 and 37.4±0.7 to 37.7±0.1 and the HCT from 37.7±1.3 to 41.0±0.3, 43.4±1.7 to 45.0±0.1 and 42.0±1.8 to 43.2±0.5°C for nymphs and adult females and males. The results indicate that nymphs of N. lugens are currently living at temperatures close to their upper thermal limits, and that acclimation ability is greater at low than at high temperature.

Environment driven changes in foraging behaviour of hyperparasitoid wasps and their impacts upon the structure of host-parasitoid networks

Dominic Charles Henri
University of Exeter, United Kingdom

In networks including herbivorous insects, top-down pressures predominantly drive community structure, so the foraging behaviours of parasitoid insects hold particular import for ecology (Morris et al., 2005). As occurs in predator-prey networks, we believe parasitoid foraging behaviour determines the distribution of strong and weak links within networks, which are important components of stability and structure (Brose et al., 2010). The effect of climate on parasitoid physiology is well documented, but there has been little consideration of how the external environment alters their behaviour; especially at a network level. Using a multi-year, quantified network, unique among entomological studies, we show that the hyperparasitoid wasp, Asaphes vulgaris, exerts greater parasitism pressure on populations of larger hosts compared with smaller hosts. A pattern thought to develop mainly from the host-choice decisions of the hyperparasitoids, and which corroborates the hypotheses of a previous optimal foraging framework (Henri & van Veen, 2011). The same framework predicts that the priorities of foraging parasitoids, and thereby link distribution are dependent upon external conditions, such as climate. Preliminary results of laboratory studies do indeed suggest that hyperparasitoids that are more constrained in their foraging time are less choosy. Our results suggest that climate change may have further implications for host-parasitoid dynamics beyond the obvious effects of changing physiology.

Assessing insect responses to climate change: How are the fingerprints being detected?

Nigel Andrew[1], Sarah Hill[2], Matthew Binns[3], MD Habibullah Bahar[4], Emma Ridley[5], Myung-Pyo Jung[6], Chris Fyfe[7], Michelle Yates[8], Mohammad Khusro[9]

[1]University of New England, Australia, [2]University of New England, Australia, [3]University of New England, Australia, [4]Agriculture and Agri-Food Canada, Canada, [5]University of York, United Kingdom, [6]National Academy of Agricultural Science, Republic of Korea, [7]University of New England, Australia, [8]University of New England, Australia, [9]University of New England, Australia

Understanding how researchers are tackling globally important issues, such as climate change, is crucial to identify whether current research is comprehensive enough to make substantive predictions about general responses to climate change. We assessed the type of studies being conducted by researchers to understand the impacts of climate change on insects, published up to June 2011. Most published research is generated from Europe and North America and being dedicated to core data analysis, with reviews being highly produced. Temperature is the main climate change driver analysed, and most researchers are assessing changes in abundance or distribution/range shifts. Highly cited studies (more than 50 citations) carry out different types of research compared to studies with less than 50 citations. Of most concern is the lack of studies focused on Hemimetabolous insect orders (which undergo gradual metamorphosis), the number of studies which do not specifically identify any climatic drivers and the need for more studies to assess specific mechanistic responses to climate change.

Bark beetles and fungi: Effects of climate change on symbiont community and stability

Diana L. Six[1], Melissa Friedmann[2], James Powell[3], Barbara Bentz[4]

[1]University of Montana, U.S.A., [2]University of Montana, U.S.A., [3]Utah State University, U.S.A., [4]Forest Sciences Laboratory, U.S.A.

Many bark beetles are involved in intimate symbioses with fungi. In some cases, the fungi contribute to beetle fitness by supplementing a nutritionally poor diet. These symbioses often involve more than one mutualistic fungal partner. These partners differ in terms of the degree of benefit they confer to the host. Thus, the relative abundance of each fungus in a population at a particular time should act to negatively or positively affect beetle dynamics depending upon which symbiont dominates. The relative abundance of the various fungal symbionts with their host beetles is strongly affected by environmental conditions, particularly temperature. This sensitivity to the environment suggests that the stability of current symbiotic partnerships will be affected as climate warms. Both beetles and fungi are ectotherms, and as such, are highly sensitive to changes in temperature. However, each organism will respond in an idiosyncratic fashion. When environmental tolerances of partners cease to overlap in a way that supports continued interaction, the symbiosis will destabilize. Such destabilization not only will affect the beetle's interactions with its environment at the microbial level, but likely also at the landscape level, and ultimately influence range expansions and contractions as a changing climate alters environmental suitability. We investigated the stability of the mutualism between the mountain pine beetle and its fungal symbionts under shifting climate scenarios. Several models were developed to illuminate the historic basis for this symbiosis and help predict its geographic and temporal viability under climate change.

Insect herbivory on eucalypts under changing resource allocations and climate change

Tara J. Murray[1], Andrew Gherlenda[2], David T. Tissue[3], David S. Ellsworth[4], Markus Riegler[5]

[1]University of Canterbury, New Zealand, [2]University of Western Sydney, Australia, [3]University of Western Sydney, Australia, [4]University of Western Sydney, Australia, [5]University of Western Sydney, Australia

Eucalypts are associated with diverse arthropod communities, including herbivorous insects that can cause severe defoliation in plantations, native woodlands and forests. Understanding the drivers for herbivorous insect populations is required to predict adaptation and design mitigation strategies that minimise future pest outbreaks and negative impacts of climate change on forest biodiversity. We utilise the Hawkesbury Forest Experiment, a climate change field experiment on eucalypts, and a series of glasshouse experiments to test responses of insect herbivores to changes of atmospheric CO2 concentrations, temperature, water availability and plant nutrition. Our results show that physiological and developmental responses of individual herbivore species to changes of a single environmental factor such as elevated CO2 are strong, yet interactions of elevated CO2 and temperature can partially mitigate the strength of these responses. On a community level though, measurement of bottom-up versus top-down regulation of herbivory on our experimental site has revealed a strong top-down control through herbivore antagonists. Any insect herbivore response and adaptation to climate change factors may in the end be strongly shaped by the higher trophic levels that so far are the least known component within Australian eucalypt communities.

Effect of climatic conditions on population dynamics of dengue mosquitoes (*Aedes aegypti* and *Aedes albopictus*).

Dr Shabab Nasir
Government College University, Pakistan

This study was carried out from 2009-2011 to know the effect of changing climatic conditions on population dynamics of Aedes aegypti and Aedes albopictus. Mosquitoes (larvae and pupae) were collected from fresh water ponds, sewage water ponds, fish ponds, rice fields, rain water ponds (rain gutters), tyres, tree holes, small water containers and manmade storage containers (drums, tanks, jars, buckets) in and around the homes present. Collection was done twice during every winter (October-February), summer (March-June) and moon soon season (July-September) from marked rural areas (fields, villages, towns) and urban areas within the area of 1 km2 of the Punjab. Immature stages were collected with dippers and adults with suckers. It was found that years, months of the year, seasons, temperature and relative humidity were important in case of population dynamics of mosquitoes. More number of mosquitoes was collected during 2010 and 2011 than other years due to heavy rains. High population (63 %) was recorded during rainy season due to high temperature (28-36 °C) and high relative humidity (up to 75 %) and very low or zero population was recorded from outside during winter due to low temperature (< 10° C) and low relative humidity (< 23 %), then the adults shifted in the rooms where they survived almost all the winter. A. albopictus was mostly recorded from rural areas but in parks of cities also found. A. aegypti was largely recorded from tyres, urban areas mostly during rainy season from small water containers.

Effect of climate change on seasonal foraging activity of termites (Isoptera)

Boris Dodji Kasseney[1], Jing Li[2], Jiqian Wei[3], Jianchu Mo[4]

[1]University of Lome (Togo), Togo, [2]Institute of Insect Sciences, Zhejiang University, China, [3]Hangzhou General Station of Plant Protection and Soil Fertilizer, China, [4]Institute of Insect Sciences, Zhejiang University, China

Seasonal foraging activity of termites depends principally on air tempera- tures which are increasing in recent years due to global warming. To examine the seasonal foraging activity of termites, a walking belt transects of 1 m wide was randomly laid every two weeks in four plots. Inside the frame of each plot, 100 wood logs were examined for the presence or absence of termites during one year. To determine the effect of temperature on termite foraging activity, the relation between the monthly mean temperatures (maximum and minimum) and the termite foraging activity were analyzed. The effect of climate change on this activity was analyzed by comparing our results with a previous study. In our study period, termites foraged throughout all the year. Their activities were low (but occurred) in winter. Foraging increased significantly in summer, reaching a maximum in autumn (especially for Od- ontoterms formosanus). Odontotermes species were the most active termites in our study sites. The species of this genus attacked 23% of the examined wood logs. Odontotermes dimorphus was also recorded for the first time in Hangzhou. The foraging activity of termites was positively correlated with air temperature. The occurrence of termite activity in winter and the presence of O. dimorphus in our study sites could be a result of global warming. We suggest that any management strategy against termites in these sites should be carried out at the period of high foraging activity.

The genomic response of grapevine to a phloem-feeding insect

Alicia Eva Timm[1], Annette Reineke[2]

[1]Rhodes University, South Africa, [2]Geisenheim Research Institute, Germany

Plants respond to insect feeding damage by regulating genes that allow the plant to defend itself in ways that ultimately limit the effects of the damage. We examined the interaction, at genomic level, between grapevine Vitis vinifera L. and a phloem-feeding insect pest, the vine mealybug Planococcus ficus (Homoptera: Pseudococcidae). Mealybugs were allowed to feed on grapevine for periods of 6 and 96 hours, after which plant transcripts were examined using microarray analysis with a 135k NimbleGen gene expression grape array. Grapevine response to mealybug feeding at intermediate periods of mealybug feeding (24, 48 and 72 hours) was investigated using qPCR analysis of ten genes known to be associated with plant defence against insects. After 6 hours of mealybug feeding, microarray analysis showed that only 107 transcripts were differentially expressed in grapevine plants. This number increased slightly to 149 transcripts after 96 hours of mealybug feeding. qPCR analysis showed that none of the genes analysed were differentially regulated after 24 and 72 hours of feeding. However, after 48 hours of mealybug feeding, a single gene, pathogenesis-related protein 1, was differentially expressed compared to control plants. Thus, both microarray and qPCR analysis showed that grapevine response to mealybug feeding was weak. In addition, microarray analysis determined that many of the genes affected by mealybug feeding are also affected by microorganism attack. This pattern indicates similar modes of evolution of resistance mechanisms against a variety of biotrophs.

Does the wooly poplar aphid, *Phloeomyzus passerinii*, manipulate the defense reactions of its host tree?

France Dardeau[1], Francoise Laurans[2], Francois Lieutier[3], Aurelien Salle[4]

[1]University of Orleans, France, [2]INRA Orleans, France, [3]University of Orleans, France, [4]University of Orleans, France

The wooly poplar aphid is a major pest of poplar stands in Southern Europe, the Near East and Northern Africa. After both intercellular and intracellular stylet pathway, it feeds exclusively in the cortical parenchyma of poplar trunks and, during outbreaks, this aphid causes extended cortical necroses and branches drying that can lead to tree death. We have compared the cortical reaction to both mechanical wounding and aphid's feeding of three Populus x canadensis genotypes with contrasted resistance levels (i.e. 'I214' which is susceptible, 'I45/51' which affects aphids' demographic parameters and 'Brenta' which impedes aphids' development). Each week during one month, we performed histological sections around stylet insertion sites to compare anatomical and biochemical modifications of bark tissues. In parallel, we have investigated how these reactions affected aphid's demographic parameters by comparing P. passerinii's development between pre-infested and control plants. Mechanical wounds induced localized wound periderms while aphid feeding triggered extended reactions, sharing similarities with a wound periderm, but exhibiting also thin-walled hypertrophied cells and typical lignins, tannins and flavanols accumulation patterns. Vacuolar phenolic compounds and lignins were more concentrated in resistant genotypes' reactions. Aphids developing on these reactions zones, after a pre-infestation, exhibited a higher rate of natural increase compared to aphids developing on uninfested host tissues. We hypothesize that P. passerinii, with its destructive feeding mode, triggers poplars defense mechanisms and manipulates them to initiate the formation of a pseudogall.

The effects of wind and bees on Pollen-mediated gene flow from transgenic *Bt* cotton

Jialin Zhu[1], Jianqun Niu[2], Qingwen Zhang[3], Xiaoxia Liu[4]

[1]China Agricultural University, China, [2]China Agricultural University, China, [3]China Agricultural University, China, [4]China Agricultural University, China

Development and commercialization of insect-resistant genetically modified (IRGM) crops expressing insecticidal proteins (Cry toxins) from bacterium Bacillus thuringiensis (Bt) have offered an alternative to traditional synthetic insecticides for control of important agricultural insect pests. Considerable discussion was addressed about the risk assessment of transgenic plants. In this study, pollen-mediated gene flow (PGF) from the transgenic Bt cotton was tested in the greenhouse. Based on PCR and protein detection, we compared the distance and the frequency of gene escape between the two treatments with wind and with bees. The results showed that the frequency of gene flow increased significantly in both wind and bees treatments compared with the treatment without wind and bees. In detection range, the maximal gene flow distance observed was 36m in both wind and bee treatments. PGF of the island cotton was higher under the condition with inconstant wind direction than that with the constant one. The rate of Bt gene expression in bee treatment was higher than that in wind treatment. These results suggest that pollen-mediated gene dispersal of cotton could enable widespread gene flow between transgenic crops and conventional varieties under current farming practice.

Distribution of *Pentalonia nigronervosa, P. caladii*, and the Banana Bunchy-Top Virus in Micronesia

Julie Anne M. Duay[1], Ross H Miller[2], George C Wall[3], Robert G Foottit[4], Keith S. Pike[5]

[1]University of Guam, Guam, [2]University of Guam, Guam, [3]University of Guam, Guam, [4]Agriculture and Agri-Food Canada, Canada, [5]Washington State University, U.S.A.

A survey of the distribution of Pentalonia nigronervosa and P. caladii, and the incidence rate of the banana bunchy top virus (BBTV) was conducted in Micronesia. Aphids and plant tissues were collected from banana and non-banana host plants in the Micronesian islands. All plant samples were tested for the presence or absence of BBTV using an enzyme linked immunosorbent assay (ELISA). Concurrently, host-switching experiments were conducted to determine the ability of the Pentalonia aphids to successfully sustain colonies upon switching from one host to another. ELISA analysis showed that BBTV is present on Guam, Saipan, Tinian, and Rota but is absent elsewhere in Micronesia. Pentalonia aphids were identified to species level using morphometric and genetic analysis. Host-switching experiments are on-going, but early trials show little successful transfers. P. nigronervosa, collected on Musa sp., occasionally transfers onto Alpinia purpurata. P. nigronervosa, collected on Musa sp., rarely transfers onto Heliconia stricta. P. caladii, collected on A. purpurata, occasionally transfers onto Musa sp. P. caladii, collected on H. stricta, rarely transfers onto Musa sp. These results of the early trials suggest that Pentalonia colonies cannot successfully maintain populations on non-host plants.

Optimal defense strategy in an extrafloral-nectar bearing plant using physical, chemical and biotic defense traits

Akira Yamawo[1], Nobuhiko Suzuki[2]

[1]Saga University, Japan, [2]Saga University, Japan

Extrafloral-nectar (EFN) bearing plants employ diverse defense tactics. Many previous studies have demonstrated that physical and chemical defenses are effective to various herbivores. However, following questions have not yet been answered: why do plants entrust defense to ant workers and how do they utilize multiple defense traits? An EFN bearing plant Mallotus japonicus possesses trichome, pellucid dot, and EFN and pearl body as physical, chemical, and biotic defense traits, respectively. In this study, we estimated the production cost of each defense trait. As a result, the increase of trichome and pellucid dot densities reduced the plant growth, whereas that of EFN and pearl body numbers did not. This indicates that the production costs of EFN and pearl body are lower than those of trichome and pellucid dot. Then we examined the effectiveness of each defense tactics. On newly extended leaves, trichome and pellucid dot densities were extremely high, but they decreased rapidly with leaf age. A laboratory bioassay revealed that trichomes and pellucid dots in young leaves acted well against herbivores, but those in middle-aged leaves did not. EFNs and pearl bodies attracted more ants on middle-aged leaves than on other leaves, but some M. japonicus plants were found to carry no ants, suggesting that the biotic defence using ants is less stable than physical and chemical defenses. The shift from the physical and chemical defenses to biotic defense with leaf age is considered to maximize the fitness of M. japonicus.

Battus philenor larvae use their frontal projections as host plant detectors

Ikuo Kandori[1], Daniel R. Papaj[2]

[1]*Kinki University, Japan,* [2]*University of Arizona, U.S.A.*

Some butterfly larvae have a pair of long projections in their frontal parts which are different from antennas. However, the role of these projections has yet to be tested. The larvae of Pipevine Swallowtail butterfly, Battus philenor, also have a pair of long fleshy frontal projections and the larvae can actively move the projections up and down. Here we hypothesized that these larvae use their frontal projections as host plant detectors while they search for host plants and tested this hypothesis. Field experiments in Santa Rita, Arizona, USA revealed that the individual plants of Aristolochia watsonii, the main host plant around this area, are rather small and scattered, that the larvae often need more than one host plant to complete their development, and therefore they have to move around to find new individual host plant after eating all of the previous individual host plant. Laboratory experiment revealed that host-plant discovery rate during searching for host plants were significantly higher for normal larvae than for the larvae whose frontal projections were cut. The visual information via lateral ocelli also contributed to increase discovery rate. To the best of our knowledge, this is the first evidence demonstrating that projections, other than legs or antennas, plays an important role of finding host plants in insects.

Gall biology of an Eulophid wasp species associated to flower ovaries of *Philodendron bipinnatifidum* (Araceae) in Brazil

Sergio Jansen[1], Simone Padua Teixeira[2], Rodrigo A. Santinelo Pereira[3]

[1]Universidade de Sao Paulo, Brazil, [2]Universidade de Sao Paulo, Brazil, [3]Universidade de Sao Paulo, Brazil

We studied between 2010-2012 the galling biology of a tetrastichine wasp (Hymenoptera: Eulophidae) that develops in inflorescences of Philodendron bipinnatifidum (Araceae). We assigned to individual inflorescences of six plants the following treatments: oviposited-pollinated (O-P), oviposited-unpollinated (O-U), not oviposited-pollinated (N-P) and Control (C). Inflorescences were protected by tissue bags to prevent natural access of insects. We recorded the abortion for each treated inflorescence and quantified the number of galled flowers/fruits and fruits with seeds. For the galling process, we introduced 30 wasps in bagged inflorescences and let them oviposit for 48h. From oviposition day we collected each 5 days 5-10 galled flowers. We destined galls to manual dissection and histology. Absence of pollination seemed to favor galling capacity. Percentage of abortion per treatment was 100% (C, n=25), 33% (O-P, n=15), 64% (O-U, n=28) and 33% (N-P, n=24). Total flowers per inflorescences was 290±112 (n=26). Number of galled flowers was 202±69 (O-U, n=7), 129±122 (O-P, n=12). Number of fruits with seeds was 280±132 (N-P, n=7) and 171±117 (O-P, n=13). Wasp egg is deposited inside the ovary locule. First larval stage (0.31±0.10mm, n=60; 5-15 days) kept egg location. Simultaneous to gall formation, second larval stage (1.19±0.47mm, n=40; 20-30 days) began to chew the integuments and established at the embryo sac cavity where it grew and achieved the final third stage (2.41±0.56mm, n=40; 35-40 days). This is the first record describing the galling biology for the group. Financial support: S.J.G. FAPESP#09/10237-9. R.A.S.P. FAPESP#04/10299-4 and CNPq#302769/2008-0. S.P.T. CNPq #301960/2009-7.

Host selection features of xylophagous insects and their applications in forest health assessment

jianmin wang[1], Xiaoming Chen[2], Zixiang Yang[3], Juan Liu[4], Fei Chen[5], Baogang Sun[6]

[1]Research institute of resource insects, Chinese academy of forestry, China, [2]research institute of resource insects, Chinese academy of forestry, China, [3]Research institute of resource insects, Chinese academy of forestry, China, [4]Research institute of resource insects, Chinese academy of forestry, China, [5]Research institute of resource insects, Chinese academy of forestry, China, [6]research institute of resource insects, Chinese academy of forestry, China

Forest health diagnosis and assessment is a rising hotspot in research and development of world forestry since 1990s. On this subject, former researchers have done some research work mainly in the aspects of forest vigor, organization, anti-menace and resilience, ecological service functions etc., however, few research papers were reported about diagnosing and assessing forest health in virtue of xylophagous insects being bioindicators based on the fact that secondary xylophagous insects prefer attacking sub-healthy and unhealthy trees. In this paper, underlying rules that secondary xylophagous insects are always in accompany with sub-healthy and unhealthy trees were explored and verified in the case of a secondary xylophagous insect-Monochamus alternatus at first. Then, suitable Pinus yunnanensis virgin forests, secondary forests and forest plantations were selected as research plots in core zone and marginal zone of geographic distribution of Pinus yunnanensis in Yunnan, China. Based on natural qualities of forest ecosystem, tree health status of Pinus yunnanensis were divided into 5 grades: healthy, sub-healthy, unhealthy, dying and dead; also, harm conditions of xylophagous insects (existing species and amount) were investigated in these plots by using bait wood and insect trap. After that, forest health index(FHI)was established to quantify forest health status. Finally, correlations and regression equations were established between forest health index of Pinus yunnanensis and harm conditions of xylophagous insects. The research aims were exploring feasibility of forest health assessment in virtue of xylophagous insects being bioindicators, and providing academic and experimental bases for assessment and sustainable management of Pinus yunnanensis forest health.

Host plant manipulation by a gall-inducing insect: Regrowth response affects on herbivores abundance

Ananto Triyogo[1], Hironori Yasuda[2]

[1]*United Grad. of Agricultural Science Iwate Univ., Japan,* [2]*Faculty of Agriculture, Yamagata University, Japan*

Insect herbivores manipulate physiology, phenology and nutrition of host plants, thus may effect on abundance and performance of other herbivores. We investigated regrowth effects by a chestnut gall wasp Dryocosmus kuriphilus, and its effect on other herbivore. A pair of 1-year old galled and ungalled shoots was randomly selected. Physical and nutritional changes in the host plant in terms of leaf thickness and toughness, and nutrition content were measured. Gall initiation stimulated the formation of new leaves and accelerated maturation leaves during May to August. Leaves emerged from galled shoots were tougher and thicker, and also had higher nitrogen but low water content. Colonization by the aphid Myzocallis kuricola was significantly higher on leaves emerged from galled shoots. Gall initiation positively affected the abundance of aphids by enhancing the availability of food resources as a result of the regrowth responses in the chestnut.

Keywords:*host-plant manipulation, regrowth response, gall-inducing insects, herbivores, Dryocosmus kuriphilus, Myzocallis kuricola*

Feeding and growth of cotton armyworm *Spodoptera litura* Fabricius (Lepidoptera: Noctuidae) in response to cotton varietal characteristics

Yong Jung Kwon[1], Md Ruhul Amin[2], Dil Afrose Tithi[3]

[1]School of Applied Biosciences, Coll. of Agr. & Life Sci., Kyungpook National University, Republic of Korea, [2]Department of Entomology, Hajee Mohammad Danesh Science and Technology University, Bangladesh, [3]Department of Entomology, Hajee Mohammad Danesh Science and Technology University, Bangladesh

This study investigated morphological and biochemical characteristics of CB9, CB10 and SR05 cotton varieties and observed their effect on feeding and growth of cotton armyworm Spodoptera litura. Morphological characters of plant architecture, branching, color, hairiness, trichome density and boll size indicated that CB9 is a bushy, well developed, branched, light bronze colored and hairy variety with number of trichomes 193/cm2 and boll weight 5.5?6.0 g/boll. Both CB9 and CB10 bear normal leaves and spherical bolls whereas SR05 has well-ventilated branching, okra shaped and ventrally arranged light bronze colored leaves and oval bolls ranging 4.0?4.5 g/boll. Biochemical analysis indicated significant differences in starch and protein contents, which range 11.4?21.3 and 17.5?30.6%, respectively. The lowest percentages of starch and protein were found in SR05 and CB9, respectively. Cotton varieties showed significant effects on second, third, fourth and fifth instar larval weight and they attained the highest weights (22.7, 133.8, 168.2 and 1190.2 mg, respectively) when fed SR05. Larvae and moths fed SR05 also showed the significantly highest cocoon, exuviae, and adult male and female weights (434.5, 19.2, 161.3 and 232.4 mg, respectively). The cotton armyworm showed the significantly highest growth index (1.5) as well as lowest feeding index (0.05) on SR05. Results of this study indicated that SR05 is suitable for larval feeding and development, and suggest that this variety is least suitable for cotton growers in areas where S. litura is a major pest.

Routes and processes leading to New World-Old World and North America-South America disjunctions in three widespread spider wasp groups (Hymenoptera: Pompilidae)

Juanita Rodriguez[1], James P Pitts[2], Carol D von Dohlen[3]

[1]Utah State University, U.S.A., [2]Utah State University, U.S.A., [3]Utah State University, U.S.A.

Ceropales, Anoplius and Aporini are three widespread groups of spider wasps. The females of these pompilids have different behaviors that range from host capturing and dragging, to the use of a host captured by another spider wasp (cleptoparasitism). Members of these groups are distributed worldwide, but the fossil record and preliminary dating analyses suggest that Pompilidae, and thus Ceropales, Anoplius and Aporini are no older than 50Ma. Because they are younger than Pangaea, Laurasia, or Gondwana, processes not related to continental drift must explain their present distribution. Our aim was to determine the age and processes that led to the cosmopolitan distribution of Ceropales, Anoplius and Aporini, and compare them. We studied the historical biogeography of these groups using molecular data to construct a chronogram, which was dated using fossils. We also estimated ancestral areas using a Bayesian approach. Our results suggest that all the groups originated in different areas in the Late Oligocene. The events leading to dispersal between the New World and Old World occurred at the same time in the Early Miocene, and the events leading to movement between North America and South America occurred between the early and middle Miocene, with some differences in timing between the groups.

A possible seasonal trade-off between the number of dispersed seeds and long-distance seed dispersal in myrmecochorous sedges, *Carex lanceolata* and *C. tristachya* (Cyperaceae)

Koki Tanaka[1], Nobuhiko Suzuki[2]

[1]Kagoshima Univ., Japan, [2]Saga Univ., Japan

Seed dispersal affects the distribution of plant individuals, and hence their fitness. Thus, clarifications of traits determining the dispersal patterns and their evolutionary mechanisms are fundamentally important. The number of dispersed seeds and seed dispersal distance, both of which are related to the dispersal success, could change seasonally with overall density and species composition of seed dispersers. Therefore, fruiting phenology should evolve to maximize the dispersal success. To test this hypothesis, seasonal changes in the overall density and species composition of dispersers must be clarified. In this study, I surveyed these two disperser attributes periodically during the fruiting periods of two myrmecochorous sedges, Carex lanceolata and C. tristachya. Then I measured seed dispersal distances by several ant species. The density of overall ants increased with date, but the proportion of Formica japonica, the largest species and a long-distance seed disperser, decreased. As a consequence, earlier fruiting of C. lanceolata synchronized with high proportion of the long-distance disperser, while later fruiting of C. tristachya did with high density of the disperser assemblage. These results indicate that interspecific differences in the fruiting period among sympatric ant-dispersed plants reflect the difference in the relative importance of the number of dispersed seeds and long distance seed dispersal.

Genetic structure and diversity of the populations of an invasive species *Cydia pomonella* (L.) (Lepidoptera: Tortricidae) in China

Maohua Chen[1], Qiulei Men[2], Jinian Feng[3], Yalin Zhang[4]

[1]Northwest A&F University, China, China, [2]Northwest A&F University, China, China, [3]Northwest A&F University, China, China, [4]Northwest A&F University, China, China

The codling moth, Cydia pomonella (L.) (Lepidoptera: Tortricidae) is one of the most serious pest insects in apple orchards. This pest was firstly reported in China in the 1950s and was considered one of the most serious invasive pest in fruit orchard. It spread rapidly from the original site in Xinjiang to other northwestern regions, and has also invaded into some northeastern regions since 2006. With its rapid invasion rate, most apple growing regions of China is being threatened. As yet there has been no research into the genetic structure and genetic diversity of codling moth populations in China. In this study, we collected C. pomonella populations throughout the invested regions of China. Microsatellites and mitochondrial genes were used to investigate the genetic structure and diversity of these sampled populations. It was observed that there was significant genetic differentiation among populations. The populations from Heilongjiang, northeastern China, revealed distinct genetic structure and higher genetic diversity in comparison with populations from Xinjiang and Gansu, northwestern China. Meanwhile, populations from northern Xinjiang showed similar genetic diversity and genetic structure, whereas the two populations from southern Xinjiang also shared similar genetic diversity and structure. Furthermore, genetic diversity of the three populations from Hexi Corridor was of the same level as the population from the adjacent region of Xinjiang. It was possoble that the northerstern populations had dfferent invasive origin of the northwestern populations. Geographic isolation, human-aided dispersaql and the flight capacity of influence population genetics of codling moth populations in China.

Role of hoverfly - plant species interaction in maintenance of pea aphid host races

Ilka Vosteen[1], Jonathan Gershenzon[2], Grit Kunert[3]

[1]Max-Planck Institut for Chemical Ecology, Germany, [2]Max-Planck Institut for Chemical Ecology, Germany, [3]Max-Planck Institut for Chemical Ecology, Germany

The pea aphid (Acyrthosiphon pisum) complex consist of at least 11 genetically distinct host races which are native to specific host plants, but can all develop on the universal host plant Vicia faba. The factors that gave rise to and maintain these host races are not yet known. If natural enemies prefer certain plants for prey searching or oviposition, this might cause aphids to favour other plants (enemy free space) as hosts and thus help to maintain the host races. The attractiveness of a certain plant for natural enemies might depend on plant architecture, volatile profile and chemical composition which may alter the nutritional value and toxin content of aphids, thereby influencing natural enemy performance. We tested for the existence of enemy free space by exposing three pea aphid host races feeding either on their respective native host plants, Medicago sativa, Trifolium pratense, or Pisum sativum, or on the universal host plant to natural predator populations in the field. For each aphid host race we found a strong oviposition preference of hoverflies (Episyrphus balteatus) for the universal host plant. Since hoverfly larvae are important aphid predators we conclude that they may force pea aphids to use other hosts. In a laboratory experiment, we monitored the performance of hoverfly larvae fed with aphids reared either on the native or the universal host plant. Interestingly, larval performance was not influenced by the plant species the aphid prey was feeding on. Thus factors other than plant chemical composition may explain the oviposition pattern.

Acquisition of plant viruses changes host plant preference of aphid vectors

Nilsa A Bosque-Perez[1], Laura L Ingwell[2], Dheivasigamani Rajabaskar[3], Sanford D Eigenbrode[4]

[1]University of Idaho, U.S.A., [2]University of Idaho, U.S.A., [3]University of Idaho, U.S.A., [4]University of Idaho, U.S.A.

Plant virus infection can alter the suitability of host plants for their aphid vectors. Most reports indicate that virus-infected plants are superior hosts for vectors compared to noninfected plants with respect to vector growth rates, fecundity and longevity. Some aphid vectors preferentially respond to virus-infected plants compared to noninfected ones, while others avoid infected plants that are inferior hosts. Thus, it appears vectors can exploit changes in host plant quality associated with viral infection. Enhanced vector performance and preference for virus-infected plants might also be advantageous for viruses by promoting their spread. Our research has focused on two of the most important members of the virus family Luteoviridae that infect wheat, [Barley yellow dwarf virus (BYDV)], or potato, [Potato leafroll virus (PLRV)], and their respective aphid vectors, the bird-cherry oat aphid, Rhopalosiphum padi, and the green peach aphid, Myzus persicae. Our recent studies have examined preferences of viruliferous and nonviruliferous aphids for virus-infected or sham-inoculated plants (plants challenged with nonviruliferous aphids). In both pathosystems, nonviruliferous aphids significantly preferred virus-infected plants, while viruliferous aphids significantly preferred sham-inoculated plants. This shift in preference from infected to noninfected plants following virus acquisition could accelerate the rate of virus spread. Ongoing work aims to determine the mechanisms causing these changes in aphid behavior and implications for virus spread. Recent findings from our research will be presented and potential impacts on vector ecology and virus disease epidemiology will be highlighted.

Effect of host plant species on bionomic and life history parameters of *Anagyrus pseudococci* Girault (Hymenoptera: Encyrtidae) a parasitoid of the mango mealybug *Rastrococcus iceryoides* Green (Homopte)

Chrysantus Tanga[1], Sunday Ekesi[2], Samira Mohamed[3], Prem Govender[4]

[1]University of Pretoria, South Africa, [2]ICIPE, Kenya, [3]ICIPE, Kenya, [4]University of Pretoria, South Africa

Anagyrus pseudococci Girault (Hymenoptera: Encyrtidae) is a solitary, koinobiont endoparasitoid of several mealybug species. The effect of five host plants (Mangifera indica L., Cucurbita moschata Duchesne, Parkinsonia aculeata L., Cajanus cajan L., and Ficus benjamina Roxb.) on host acceptability for oviposition and suitability for immature development of this parasitoid in the invasive mango mealybug Rastrococcus iceryoides Green (Homoptera: Pseudococcidae) was investigated. Effect of host plant on fitness trait (parasitoid size, egg load and longevity) and life table parameters was also assessed. Although, A. pseudococci accepted the mealybugs regardless of the host plant, the level of acceptability varied significantly. The highest percentages of parasitized nymphs were recorded on C. moschata, P. aculeata, and M. indica, while it was lowest on F. benjamina. Host suitability was also strongly affected by the host plant and largely mirrored host acceptability for all the parameters evaluated. Female wasps reared on mealybugs maintained on C. moschata and P. aculeata were biggest and more fecund, while those reared from mealybugs maintained on F. benjamina were of inferior quality with regard to all fitness parameters evaluated. Anagyrus pseudococci achieved a greater intrinsic rate of natural increase (rm), net reproductive rate (Ro), finite rate of increase (λ) in addition to a shorter mean generation time (G) and population doubling time (Td) on mealybugs maintained on C. moschata and the reverse was true for those maintained on F. benjamina. The findings are discussed in view of improvement of laboratory mass rearing, as well as field enhancement of the parasitoid performance

The relationship between age and learning ability of *Venturia canescens*

Yasaman Moghaddasi[1], Hossein Kishani Farahani[2], Ahmad Ashouri[3], Martin Shapiro[4]

[1]University of Tehran, Iran, [2]University of Tehran, Iran, [3]University of Tehran, Iran, [4]California state university, U.S.A.

Several different physiological and biological differences occur in adults while they get ageing. In most cases ageing can affect efficacy of living organism negatively and lead to decrease organism performance. V. canescens spawn in sexual and asexual way but in most cases it occurs in asexual system and all offspring will be female. Males are too rare and observed rarely. This species is considered as one of the most important parasitoids of Pyralid moths. This survey was conducted to study ageing effects on learning ability and differences in this ability on different adults' age. Thirty fifth age larvae of flour moth were introduced to boxes (20×8 cm) and 20 one day old and naive adult wasps were introduced to these boxes and were maintained in odor tanks for five hours. Peppermint odor was pumped into the tanks, and then olfactory responses of wasps were tested in Y maze olfactometer. According to our results olfactory learning ability decrease in response to adults ageing, from one day old to fourth day old, responses curve showed a decrease with a lesser extent while it decreased extremely after forth day old. According to obtained results no significant differences observed in learning ability of wasps after forth day old.

Movement of parasitized aphids favour inbreeding avoidance of adult parasitoids

Delphine Bourdais[1], Thierry Hance[2]

[1]Universite catholique de Louvain, Belgium, [2]Universite catholique de Louvain, Belgium

In insect, mating strategies depend notably on the spatial and temporal emergence pattern of adults. In quasi-gregarious parasitoids, adults emerge from patchily distributed hosts and the rhytmicity of their emergence favour on-patch mating. Aphid parasitoids are considered to behave as quasi-gregarious species because of the patchy distribution of their hosts, but no evidence of the patchy and synchronized distribution of emergences has been proved to that date. We used a tri-trophic system composed of Aphidius matricariae (Hymenoptera, Braconidae), the aphid host Myzus persicae and turnip as host plant to investigate if this species behaves more as a solitary species or as a quasi-gregarious one because of the aphid behaviour after parasitism and the daily rhythmicity of emergences. We first observed that the immediate consequence of a female parasitoid attack on the aphid colony is aphid dispersal. As a consequence, adult parasitoids often emerge from mummies that are not distributed in patches in the environment and have to disperse to find a mate. Second, the solitary emergence of adults is reinforced by the observation of their daily rhytmicity of emergence. For a same cohort of parasitized aphids, emergences spread over 3 days and males emerge in average before females, resulting in a delay emergence of brothers and sister. We will discuss the adaptative values of both spatial and temporal emergence structures and how can it favour our understanding of the mating system and strategies of aphid parasitoids.

Nesting habit of *Osmia orientalis* and its parasitoids *Chrysura hirsuta*

Tomoyuki Yokoi[1], Takuto Hirooka[2], Mayumi Tamaru[3], Ikuo Kandori[4]
[1]Okayama University, Japan, [2]Kyushu University, Japan, [3]Kinki University, Japan, [4]Kinki University, Japan

Osmia bees are important pollinator for crop production. Nest biology and natural enemy has been investigated in many species that nesting in woods and stems. However, little is known about the nesting habitats of Osmia bees nesting in snail shells and the parasitism by cuckoo wasps. We investigated 1) the nesting rate of Osmia orientalis Benoist and 2) the rate of parasitism and sex ratio of the cuckoo wasp Chrysura hirsuta (Gerstaecker) that only parasitizes O. orientalis in Japan. We successfully led them to nest in the empty snail shells which we placed in the field. As a nesting environment, they preferred glass fields rather than denuded, adjacent to buildings, or forest edge. The nesting rate was higher for larger shells of Euhadra amaliae than for smaller ones of Satsuma japonica. The rate was also higher for intact shells than for damaged ones. The overall sex ratio within the shell nests was rather male biased. Sex distribution within the shell nests was difference with shell species. The female ratio gradually increased towards the outer cells and became highest in the second outer cells. The percentage of parasitism by cuckoo wasps per all collected cocoons tended to be high (20-50%). From our results and previous reports, the adult sex ratio of C. hirsuta was strongly female-biased, which suggests that the species reproduces via thelytokous parthenogenesis. Further work would reveal both nesting strategy of O. orientalis and reproductive strategy of C. hirsuta.

Why does *Oreina cacaliae* (Coleoptera: Chrysomelidae) take the decision to fly and leave its host plant?

Nicole Marguerite Kalberer Simmen
University of Basel, Switzerland

In the Swiss Alps a population of the Chrysomelid Oreina cacaliae has been observed for several years, where one part of the population engages in flight in autumn and spring, whereas the other part does not fly. Here we address the question if costs are associated with the decision to fly. Factors like number of larvae produced, life span, and mating success were analyzed. We found that flyers were smaller in size and lighter in weight than non-flyers. Smaller female beetles were reduced in larvae production compared to bigger ones. We found that non-flyers lived longer and produced more larvae than flyers. Wing size analysis showed no difference between flyer and non-flyer groups. Behavioural mating experiments showed that heavy beetles (males as well as females) were more successful in (multiple) mating than lighter ones. To our surprise freshly emerged new generation females did not have higher mating success than older females. Can it be that the lighter/smaller beetles decide to leave the host plants by flight because they have a reduced fecundity and are less successful as mating partners?

Senescence in immune priming and attractiveness in *Tenebrio molitor*

Tatjana Krama[1], Janina Daukste[2], Inese Kivleniece[3], Markus J. Rantala[4], Indrikis Krams[5]

[1]University of Daugavpils, Latvia, [2]University of Daugavpils, Latvia, [3]University of Daugavpils, Latvia, [4]University of Turku, Finland, [5]University of Daugavpils, Latvia

Age-related decline in immune activity is referred to as immunosenescence and has been observed for both the adaptive immune response of vertebrates and the innate immune system of invertebrates. Since maintaining a basic level of immune defence and mounting an immune response is costly, optimal investment in immune function should vary over a wide range of individual states such as the individual's age. In this study we tested whether the immune response and immunological priming within individuals become less efficient with age using mealworm beetles, Tenebrio molitor, as a model organism. We also tested whether aging and immunological priming affected the odours produced by males. We found that young males of T.molitor were capable of mounting an immune response a sterile nylon monofilament implant with the potential to exhibit a simple form of immune memory through mechanisms of immune priming. Older males did not increase their immune response to a second immune challenge, which negatively affected their sexual attractiveness and remaining life span. Our results indicate that the immune system of older males in T.molitor is less effective, suggesting complex evolutionary trade-offs between ageing, immune response and sexual attractiveness.

Sexual pheromones evolution in insular bumblebees

Thomas Lecocq[1], Denis Michez[2], Audrey Coppee[3], Simon Dellicour[4], Irena Valterova[5], Jean-Yves Rasplus[6], Pierre Rasmont[7]

[1]University of Mons, Belgium, [2]University of Mons, Belgium, [3]University of Mons, Belgium, [4]Universite Libre de Bruxelles, Belgium, [5]Academy of Sciences of the Czech Republic, Czech Republic, [6]Institut National de la Recherche Agronomique (INRA), France, [7]University of Mons, Belgium

The courtship signal allows pre-mating recognition. Its evolution depends on the sexual selective pressure mainly lead by interspecific interactions. In sympatry with Closely Related Species (CRS), the selection for specific signals to avoid mismatch make this pressure stabilizing. This leads to a saltational evolution across phylogenetic lineage. Conversely, in allopatry with CRS, as in many insular systems, the lack of hydridization risk may promote relaxation of the stabilizing selection and change the courtship signal evolution. We tested this hypothesis using genetic and chemical comparative approaches on a courtship signal trait, the Sexual Marking Pheromones (SMP) of four bumblebee species including Corsican insular (allopatry with CRS) and mainland (sympatry with CRS) populations. Analyses showed 1) genetic and SMP differentiation of insulars and, 2) a lower genetic variability and a higher SMP variability of insulars. A correlation between the neutral loci distance and the SMP distance was detected for the insulars. Differentiation of Corsican bumblebees has led to rapid speciation in ca 15 000 years. The increase of the SMP variability and the correlation genetic-SMP suggested a relaxation of the stabilizing selection on the courtship signal leading to a gradual differentiation in insular system with species free of their CRS.

How do insects find differently sized realistic odour plumes? Model and experiment

Lia Hemerik[1], Marjolein Lof[2], Peter Hamback[3]

[1]Biometris, Wageningen University, Netherlands, [2]Biometris, Wageningen University, Netherlands, [3]Stockholm University, Sweden

Chemical information is the main basis for insects to gather information about the value of their environment. The chemicals conveying information are known as infochemicals. The wind disperses odour molecules from a substrate into the environment. The structure of such an odour plume is varying over time. At a small scale the plume has an intermittent structure: patches with high odour concentrations are interspersed with regions with no odour at all. The full odour plume meanders as it moves with the wind. Here, we compare the odour concentrations of a so-called filamentous plume model that takes the features of a real odour plume into account, with measurements from experiments on detection of odours by insects. We also investigate how settlement of insects differs with the size of an odour plume and the threshold value for detection of the odours by the insects.

Keywords:*filamentous plume, Gaussian plume, spatial distribution, settlement, odour source discrimination*

Effect of migration and mating status of the legume pod borer, *Maruca vitrata* (Fabricius) (Lepidoptera: Crambidae) on the efficacy of synthetic sex pheromone traps in West Africa

Taro Adati[1], Manuele Tamo[2], Shinsaku Koji[3], Mark C. A. Downham[4]

[1]Tokyo University of Agriculture, Japan, [2]International Institute of Tropical Agriculture, Benin, [3]Kanazawa University, Japan, [4]Natural Resources Institute, United Kingdom

Synthetic sex pheromone traps for the legume pod borer, Maruca vitrata, effectively attracted males in cowpea fields at Cotonou in southern Benin, where pest incidence is observed throughout the year. However, the same pheromone lures caught very few moths in areas north of latitude 9° N in Benin, Nigeria and Niger, despite the fact that there were a large number of catches in light trap collections. To clarify the relationship between reproductive ability and migration in M. vitrata, sex and female mating status of the individuals caught by light traps were examined. The results showed that light-trap catches were more female-biased from August to October, a peak period of the moth population, at Kandi and Kano. After October, the female-ratio decreased in Kano. In contrast, the Cotonou population was male-biased from July to August, and shifted to a female-bias from November to January. The proportion of mated females was higher at the beginning of incidence at Kano, before the mating rate decreased after September. A hypothesis was presented to explain the seasonal changes in reproduction and migration of the pest as follows: M. vitrata moths are sexually active in the south humid zone, thus they can mate. After mating, more female moths migrate from south to north, while fewer males migrate. The immigrants and their offspring are sexually inactive in the dry zone for unknown reasons. These might be part of the reason why pheromone traps are not effective for M. vitrata males in the dry savanna of West Africa.

Pheromones and body coloration affect mate recognition in *Amata* genus

Yusuke KonDo[1], Hideshi Naka[2], Koji Tsuchida[3]

[1]Laboratory of Insect Ecology, Japan, [2]Laboratory of Applied Entomology, Japan, [3]Laboratory of Insect Ecology, Japan

Japanese nine-spotted moth Amata fortunei and related species A. germana were diurnal moths and sympatric. We observed that A. fortunei males flow in the early morning, while A. germana males did in the late afternoon. Adults have different body colorations: A. fortunei have two yellow bands on the 1st and 5th segments of their abdomens (two-band type); A. germana have yellow bands on each segment (each-band type). To evaluate the importance of visual cues in mating behavior, we conducted the experiments with crude extract and an additional model stimulant. A. fortunei males responded more to model females with the same number and a similar area of yellow bands to the original conspecific females than to those with more bands and a greater total band area, suggesting that a dissimilarity in band number and area to conspecific females could interrupt male mating behavior. On the other hand, A. germana males responded to females A. fortunei as same as conspecific females, suggesting that importance of visual cues in mating behavior of A. germana could less than that of A. fortunei. In conclusion, two species have different time schedules for mating and different sex pheromone components are involved (KonDo et al. unpublished data). These suggest that both differences in pheromone components and body coloration played a role in speciation within the genus.

Behavioral and chemical differences among females in the temperate paper wasp *Polistes snelleni*.

Kazuhisa Yamasaki[1], Koji Tsuchida[2]

[1]*Laboratory of Insect Ecology, Japan,* [2]*Laboratory of Insect Ecology, Japan*

Polistes wasps are primitively eusocial insects with less specialized female castes. In their societies, aggressive behaviors among females play important roles to regulate their reproductive hierarchies. In addition, cuticular hydrocarbon profiles (CHCs) reliably provide information about the fertility differences among the females. Previous studies have suggested that unmated egg-laying workers in orphaned colonies produce CHCs resembling to those of queens. It has been predicted that caste determination in Polistes wasps should be absent or occur in post-emergence period because workers seem to be totipotent. Workers of Polistes snelleni are capable of reproducing female offspring directly via fertilized eggs. We compared behaviors and CHCs of females in queenright and orphaned colonies. Egg-laying workers in orphaned colonies showed aggressive behavior more frequently than queens. In addition, there were differences in CHCs between queens and workers. Although mated egg-laying workers showed rather similar CHC profiles to queens' CHCs, those of other workers were far distinct from queens'. These results suggest that the CHC profiles of the female wasps are honest signals reflecting their fertility and caste differences. Because there were behavioral and chemical differences between queens and workers, mating status seems to be determinant effect on the females status in P. snelleni.

Changes in apple plant volatiles in response to feeding damage of *Pandemis heparana*

Valentino Giacomuzzi[1], Sergio Angeli[2]

[1]Free University of Bolzano, Italy, [2]Free University of Bolzano, Italy

The volatile organic compounds (VOCs) emitted by the leaves of young apple seedlings of Golden Delicious were collected by close loop stripping analysis and characterized by the gas-chromatography mass-spectrometry. Volatile emissions were taken from undamaged, mechanically damaged and insect damaged seedlings. The insect damaged seedlings were previously infested with ten larvae (IV instar) of one of the major apple pests, namely the moth Pandemis heparana (Lepidoptera: Tortricidae). Volatiles were collected for three subsequent days. In the headspace of undamaged plants 12 volatile compounds were indentified, among which the green-leaf-volatiles (Z)-3-hexenyl acetate and ethyl-hexanol, together with the aldehydes nonanal and decanal. In case of mechanically damaged leaves 18 compounds were detected, where (Z)-3-hexenyl acetate represented the highest peak. Some compounds, as acrolein diethyl acetal, (E)-4,8-dimethyl-1,3,7-nonatriene, (Z)-3-hexenyl butyrate, (Z)-3-hexenyl benzoate, indole and α-farnesene were found in the headspace of mechanically damaged plants but not in healthy plants. Six hours after damage (Z)-3-hexenyl acetate concentrations strongly decreased. In the headspace of seedlings damaged by P. heparana 26 volatile compounds were characterized. Among them, some VOCs were uniquely induced, as the monoterpene (E)-β-ocimene, the terpene alcohol linalool, the sesquiterpenes β-caryophyllene and germacrene D, the sesquiterpenoids calamenene and cadalene, the benzenoids benzyl cyanide and methyl-salicylate. Our results clearly showed, for the first time, that apple trees strongly changed their volatile emission profile as a result of a specific, herbivore-induced response to P. heparana damage.

Use of immunomarking to determine foraging patterns of *Osmia cornifrons* (Radoszkowski) in a cherry orchard

Neelendra K. Joshi[1], David J. Biddinger[2], Edwin G. Rajotte[3], Noemi O. Halbrendt[4], Cassandra Pulig[5], Kusum J. Naithani[6]

[1]Penn State University Fruit Research & Extension Center, U.S.A., [2]Penn State University Fruit Research & Extension Center, U.S.A., [3]Penn State University, U.S.A., [4]Penn State University Fruit Research & Extension Center, U.S.A., [5]Penn State University Fruit Research & Extension Center, U.S.A., [6]Penn State University, U.S.A.

Foraging patterns of bee species should be understood for proper placement of nest sites and to ensure adequate pollination. Field and laboratory studies were conducted to quantify the foraging patterns of Osmia cornifrons (Radoszkowski) (Megachilidae, Hymenoptera) with an immunomarking method in a commercial cherry orchard in Pennsylvania. Individuals of O. cornifrons were marked with egg-white protein powder and released from a dispenser nest placed at the center of the study orchard at early stage of bloom. After 30 h of foraging, samples were collected from randomly selected sampling cherry trees located at different distances (up to 55 m) in all directions from the O. cornifrons dispenser nest. Samples were analyzed for the presence of immunomarker protein with enzyme-linked immunosorbent assay. Foraging patterns were determined by calculating the distance and direction of marked flowers from the nest. The proportion of protein marked samples for each tree was compared with the tree's distance and direction from the nest and fruit density per limb cross-sectional area (cm2). At harvest, fruit density in the test orchard was compared with fruit density in a control orchard that did not have O. cornifrons. A high percentage of sampled flowers were protein-marked up to 40 m radius. Percentage of marked flowers dropped markedly between 41 and 55 m from the nest. Fruit density per limb cross-sectional area was significantly higher in the orchard with O. cornifrons compared with the control (P = 0.000), indicating valuable pollination services of O. cornifrons in cherry orchards.

Exotic omnivore dung is more attractive to native North American dung beetles than North American herbivore dung

William Wyatt Hoback[1], Sean D Whipple[2]

[1]University of Nebraska at Kearney, U.S.A., [2]University of Nebraska at Kearney, U.S.A.

Although the preference of dung beetles (Coleoptera: Scarabaeidae) for specific types and conditions of dung has been given substantial attention, little has been done to investigate the potential effects of exotic mammal introduction for game farms or rewilding projects. We used pitfall traps baited with various native and exotic herbivore, carnivore, and omnivore dung to evaluate dung beetle preference in the Great Plains of North America. Additionally, we analyzed of the nutrient quality of each dung type. In total, 9,089 dung beetles from 15 species were captured in 2 years of sampling. We found significant differences ($P<0.05$) in mean dung beetle capture among omnivore, herbivore, and carnivore dung, as well as differences in individual species preference for dung type. Omnivore dung was the most attractive with chimpanzee and human dung having the highest mean capture (291.1 + 27.6 and 287.5 + 28.5 respectively). Carrion also was highly attractive with a mean of 231.9 + 20.6 beetles per trap (N=8). Our results suggest definitive local preference of carrion in Phanaeus vindex Macleay and Onthophagus hecate (Panzer), while the congener, O. pennsylvanicus (Harold), was rarely captured in carrion and highly preferred omnivore dung. Preference for a specific bait type does not appear to be correlated with dung quality, mammalian diet, or origin of mammal. Results suggest niche segregation by dung type among dung beetle species.

Attractiveness of fermenting baits to tortricid moths in fields in Korea and New Zealand

KyungHee Choi
National Institute of Horticultural & Herbal Science, Republic of Korea

The attractiveness of different rice wines and fruit-based fermenting baits to various moth species was assessed in Korea and New Zealand in 2010 and 2011. In Korean apple orchards, the major lepidopteran pests such as Adoxophyes para orana, Choristoneura longicellana and Grapholita molesta were attracted to the fermenting baits. Adoxophyes para orana showed the highest trap catches with the fermenting baits in the Korean apple orchards, and four other leafroller species were also captured in the fermenting baited traps. Among the different fermenting baits tested in Korean apple orchards, 'Ga-pyung-jat' rice wine- and pineapple-based fermenting baits showed higher attractiveness to A. para orana and other leafrollers than fourteen other rice wine-based or six other fruit-based fermenting baits. In an apple orchard and a pine forest in New Zealand, the attractiveness of rice wine-, plum- and peach-based fermenting baits to Epiphyas postvittana and other moths was higher than golden syrup- or molasses- based fermenting baits. The attractiveness of the fermenting baits to Epiphyas postvittana increased when added with sucrose. The binary mixture of rice wine- and peach- or plum-based fermenting baits were more attractive to the leafrollers than the individual fermenting baits. The attractiveness of the rice wine- and fruit-based fermenting baits to the leafrollers forms the base of our ongoing efforts to develop generic attractants for leafrollers in orchards.

Would female oviposition preference affect larval anti-predator defenses? A case study using a polyphagous aquatic lepidopteran species

Ling-Ying Tsai[1], Shen-Horn Yen[2]

[1]National Sun Yat-Sen University, Taiwan, [2]National Sun Yat-Sen University, Taiwan

In a polyphagous herbivorous insect species, host determination happens in both adult and larval stages. For those species whose neonates are considered less mobile, the ability of adult female to accurately locate and choose oviposition site is considered to affect the initial survival and development of newly hatched larvae. Here we report a case based on a polyphagous aquatic moth, Parapoynx crisonalis, whose caterpillars build portable cases with host plant leaves in order to reduce predation risk. It is expected that females lay more eggs on the plant which is suitable for larval development and case making instead of investing her eggs by chance. We firstly analyzed the growing types of the plants utilized by P. crisonalis by literature review and field analysis, and carried out a choice experiment to test whether adult female oviposition is biased on different host plants. Meanwhile, survival rate, development time of each instar, pupa mass, and average shelter building time of 10 larvae on each host species were recorded to evaluate whether adult's host plant choice corresponds with larval feeding and case-making performances. Our results suggest that while P. crisonalis were recorded feeding on a variety of aquatic plants, they were actually confined to only some floating plants probably due to its stereotypical building behavior. In addition, differences in thickness and shapes of leaves would affect the time and energy cost in shelter building and may be a main factor for host determination.

Characterization of resistant factors in faba bean (*Vicia faba* L.) cultivars against cowpea aphid (*Aphis craccivora* Kosch.) using Electrical Penetration Graph (DC-EPG)

Alan Soffan[1], Salem Safer Alghamdi[2], Abdulrahman Saad Aldawood[3]

[1]*Economic Entomology Research Unit, Saudi Arabia,* [2]*College of Food and Agriculture Science, Saudi Arabia,* [3]*Economic Entomology Research Unit, Saudi Arabia*

Potential resistance of five faba bean, Vicia faba L., cultivars against cowpea aphid, Aphis craccivora Kosch. (Hemiptera:Aphidae) was characterized through colony-development study, biological study, and feeding behaviour study using Electrical Penetration Graph (DC-EPG). The last two experiment were conducted by distinguishing whole plant (WP) and detached leaf (DL) assays. Colony-development study ranked the cultivars from the highest resistance to susceptible level into Gazira 2>Commercial 'Misr'>Giza 3 improved>Goff 1>Misr 1. Total progeny number for most of cultivars except Giza 3 improved, showed significantly different between whole plant and detached leaf as shown in biological study. Feeding behaviour study revealed that the different resistant levels among five faba bean cultivars were not due to phloem tissue factors or leaf surface factor, as confirmed by the scanning electron microscope (SEM). The resistance factor especially in whole plant Gazira 2, rather because of the longer duration of stylet derailment (waveform F), however, it was not retained in detached leaf. Principle component analysis for some selected feeding parameters showed the significant difference in aphid performance between whole plant and detached leaf. The combination of colony-development and feeding behaviour studies using DC-EPG shown to be an effective way to locate the resistant factor in faba bean cultivars against cowpea aphid.

Functional significance of fruit fly (Bactrocera: Tephritidae) male attractants and underlying genetic mechanisms

Kumaran Nagalingam[1], Peter Prentis[2], Solomon Balagawi[3], Mark Schutze[4], Anthony R Clarke[5]

[1]Queensland University of Technology, Australia, [2]Queensland University of Technology, Australia, [3]Queensland University of Technology, Australia, [4]Queensland University of Technology, Australia, [5]Queensland University of Technology, Australia

Male attractants are widely used in the monitoring, control and eradication of Bactrocera fruit flies. Despite their importance in pest management, the functional role of attractants is known for only a few, predominantly methyl eugenol (ME) responsive, species. Most studies for ME flies suggest a role of the attractants in male courtship behaviour, with females showing preference for males that have ingested the attractants. In contrast to the better studied ME responsive species, we have studied the functional effects of cuelure (4-[4-acetoxyphenyl]-2-butanone) and zingerone (4-(4-hydroxy-3-methoxyphenyl)-2-butanone) on B. tryoni lure-fed males and females that have mated with lure-fed males. We recorded male mating success, remating success, remating behaviour and longevity, and female mating refractoriness, fecundity, egg viability and longevity. Mating success by lure-fed males suggests preferential selection of lure-fed males by virgin females, but the effect was short-term. Further, preferential mating success was not evident when using non-virgin females. When given opportunity for daily mating, a relatively high proportion of lure-fed males remated. Females remated less after mating with lure-fed males and had higher fecundity, but there was no apparent effect on egg viability. Both lure-fed males and females mated with lure-fed males, showed increased mortality levels. We speculate the attractants are modifying sperm quality and seminal proteins that induce sexual and physiological changes in the females. We are also undertaking transcriptome analysis of lure-fed and unfed flies to correlate genetic changes with observed behavioural and physiological changes.

Reversal in ecological host race formation in western populations of *Rhagoletis pomonella*

Sheina Biason Sim[1], Jeffrey Feder[2], Scott Egan[3]

[1]University of Notre Dame, U.S.A., [2]University of Notre Dame, U.S.A., [3]University of Notre Dame, U.S.A.

A major goal of biological research is to understand how populations diverge to become separate species. The apple maggot fly, Rhagoletis pomonella (Diptera: Tephritidae), has made several important contributions to our current understanding of ecological speciation and host race formation due to its rapid host shift in the eastern United States from historically infesting native hawthorns (Crataegus mollis) to introduced apples (Malus pumila) in the last 150 years resulting in apple and hawthorn host races. Previous studies have shown that host races differ in phenology (adult eclosion time) and host odor discrimination of adult flies and exhibit large areas of genetic divergence within the genome. Recent introduction of apple flies to the western United States has initiated the development of an interesting twist to the natural history of R. pomonella when it made a reversal in host shift back from infesting apples to infesting two separate western hawthorn species (C. douglasii and C. monogyna) where there were previously no known apple maggot infestations. We conducted field experiments that provided evidence for differences in host odor discrimination between western flies infesting the three different western hosts. In addition, I have found evidence for population structure between flies infesting the three different hosts. These results provide evidence for recent genetic divergence between recently formed host associated populations., which can be a prelude to the formation of host races and is a process that has been argued to have produced the entire R. pomonella sibling species complex of five or more taxa.

Genetic diversity and population structure of *Bactrocera correcta*, from China, Thailand, Myanmar and Laos based on mtDNA COI

nopparat buahom[1], Yu Du[2], Yi Wu[3], Yuliang Deng[4], Jiaqi Liu[5], Xiaolong Jiang[6], Zhihong Li[7]

[1]China Agricultural University, China, [2]Yunnan Entry-Exit Inspection and Quarantine Bureau, China, [3]Chinese Academy of Tropical Agricultural Sciences, China, [4]Xishuangbanna Entry-Exit Inspection and Quarantine Bureau, China, [5]General Administration of Quality Supervision, Inspection and Quarantine, China, [6]Yunnan Entry-Exit Inspection and Quarantine Bureau, China, [7]China Agricultural University, China

The guava fruit fly, Bactrocera (Bactrocera) correcta (Bezzi) (Diptera: Tephritidae) is one of the most serious insect pests of fruits and vegetables in Tropical and Subtropical regions, and regarded as quarantine pests in many countries. At present, this fly is mainly distributed in Southeast Asia. In this study, we analyzed genetic diversity and population genetic structure of the 17 populations of B. correcta collected from four countries, including China, Thailand, Myanmar and Laos using a 615-bp-long mtDNA COI sequence. Our analysis suggest that populations from Thailand showed the highest levels of genetic diversity, especially the Chiang Mai population possessed the highest levels of both haplotype diversity and nucleotide diversity, and shared an ancestral haplotype, H16. Mantel test showed that it had no isolated-by-distance effect. Fst values of all 17 populations ranged from -0.083 to 0.457, and 60.29% of it differed non-significantly, showing notable gene flow among these populations, especially between the Chiang Mai (Thailand) population and the Mengla, Kunming and Jinghong populations from Yunnan, China. This study suggests that the B. correcta populations from Thailand-Chiang Mai had a close relationship to ancestral populations. High levels of genetic diversity in Mengla indicate that this region is highly possible to be one of the entry points of this fly to Yunnan.

Variation among ancestral populations of a global superpest: The case of the Colorado potato beetle

Yolanda H. Chen[1], Victor Izzo[2], Jordan Armstrong[3]

[1]University of Vermont, U.S.A., [2]University of Vermont, U.S.A., [3]University of Vermont, U.S.A.

Invasive species species are successful examples of rapid evolution. Approximately 40% of the major agricultural insect pests in the US are introduced insect pests that have host-shifted onto crop plants, and collectively they cause major economic losses to each year. Host shifts onto crop plants can be transformative events for insect pests, resulting in rapid evolution in response to novel selective pressures. One largely unresolved factors is the determination of whether the ability to utilize novel hosts evolves during colonization of new environments or selection upon ancestral variation. The Colorado potato beetle (CPB), Leptinotarsa decemlineata, is the most persistent and damaging potato plant defoliator within the USA, Europe, and Asia. L. decemlineata first encountered the cultivated potato, when it host?shifted onto the potato in the central US in the mid?1800's. Given its success in exploiting potato agroecosystems globally, it is striking that L. decemlineata has not established on cultivated Solanaceous plants in Mexico, the likely region of origin for the beetle. We examined if there could be geographic variation in host use among ancestral beetle populations. We have found that larvae from different Mexican populations may vary in their ability to use potato as a host. Also, adult females also vary in their ability to utilize potato as a host. Therefore, significant phenotypic variation exists among ancestral Mexican populations in terms of their ability to utilize potato as a host plant.

Expression profiles of esterase genes in environmental adaptation of the brown planthopper, *Nilaparvata lugens* Stal

Hongwei Yao[1], Yan Guo[2], Mingxing Jiang[3], Yanyuan Bao[4], Zengrong Zhu[5], Gongyin Ye[6], Jia'an Cheng[7]

[1]Zhejiang University, China, [2]Zhejiang University, China, [3]Zhejiang University, China, [4]Zhejiang University, China, [5]Zhejiang University, China, [6]Zhejiang University, China, [7]Zhejiang University, China

To explore the possible functions and mechanisms of esterase genes in the environmental adaption of the brown planthopper, Nilaparvata lugens Stal, expression profiles of esterase genes in different populations treated with rice varieties, nitrogen applications and temperatures, respectively, were determined by quantitative PCR (qPCR). Twenty-four esterase ESTs which were previously sequenced from N. lugens cDNA library and three esterase genes available in GenBank, i.e. Nl-EST1(AF302777), AChE (AJ852420) and JH esterase (EU380769), were used to design qPCR primers, while β-actin served as the internal control gene. Effects of the rice variety including TN1 (a insect-susceptible indica variety), IR64 (a local indica variety in tropical areas), Xiushui 11 (a local japonica variety in China), and Liangyou 363 (a local hybrid variety in China), the nitrogen content in rice plants with low and high levels, and the temperature of 21oC, 25oC and 29oC on the expression pattern of esterase genes in adults of N. lugens populations collected from Zhejiang and Guangxi, China and Phitsanulok, Thailand, respectively, were highly significant. Generally, these esterase genes could be divided into 3 groups, according to their temporal expression patterns in response to environmental changes. The results confirm that esterase genes are involved in the environmental adaptation of N. lugens and have different function on the adaptation of N. lugens to environmental conditions. Cluster analysis showed a close relationship between Phitsanulok population and Zhejiang population.

Keywords:*Nilaparvata lugens, esterase gene, expression profile, rice variety, nitrogen content, temperature, quantitative PCR, environmental adaption*

Effects of a plant-accumulated pollutant on the gustatory behaviors, survival and pollination ecology of the honey bee (*Apis mellifera* L.)

Kristen R Hladun[1], John T Trumble[2]

[1]*University of California - Riverside, U.S.A.*, [2]*University of California - Riverside, U.S.A.*

Selenium (Se) has contaminated soils and plants in the western USA and other areas worldwide where pollination can be critical to the functioning of both agricultural and natural ecosystems, yet we know very little about how pollutants can impact insect pollinators. The overall goal of this study was to investigate both the sublethal and lethal effects of a plant-accumulated pollutant on a common insect pollinator. Using a plant species known to accumulate Se in the pollen and nectar, we conducted a two-year field study examining the pollination ecology of a common, weedy plant (radish, Raphanus sativus L.) and its pollinator, the honey bee (Apis mellifera L.). Se-treated plants remained attractive to honey bees and were not pollen limited. In laboratory studies, bees were fed four forms of Se (selenate, selenite, selenomethionine and selenocysteine) dissolved in sucrose solution and sucrose response threshold was quantified using the proboscis extension reflex. Inorganic forms of Se had sublethal consequences on the bee's gustatory behaviors. In toxicity bioassays, honey bee larvae were fed the same four forms of Se in artificial diet and survival was quantified. Inorganic forms of Se were most toxic to foragers, whereas organic forms were toxic at higher concentrations. Given that pollinators such as the honey bee cannot avoid Se compounds in the plant tissues they are foraging on, they will suffer similar adverse effects as seen in other insect guilds.

Arsenic accumulation, sequestration, and biotransformation in aquatic Diptera

Christina Loraine Mogren[1], Samuel M Webb[2], John T Trumble[3]

[1]University of California, Riverside, U.S.A., [2]Stanford Synchrotron Radiation Lightsource, U.S.A., [3]University of California, Riverside, U.S.A.

While the affects of arsenic (As) on mammals have been widely documented, relatively little attention has been allotted to how insects are affected by and respond to As exposure. The aquatic insect Chironomus riparius (Diptera: Chironomidae) has been shown to be moderately tolerant to chronic As exposure at environmentally relevant concentrations, but the means by which it is able to withstand exposures has not been examined. As a first step in assessing detoxification mechanisms, larvae of C. riparius were reared in water containing 0 or 1000 µg As (V)/l. Early and late instar larvae, as well as pupae, adults, and egg masses were analyzed using micro-XAS to map the presence and distribution of As in the samples. Points within each sample were further analyzed to determine As speciation. Whole body imaging revealed that the majority of As appears in the midgut of early and late instar larvae, with As(V) being the major constituent. As(III) and As(III)-glutathione, an organoarsenical, were also present, indicating that the ability of C. riparius larvae to detoxify As is mediated by glutathione. Adults contained only As(V) and As(III)-glutathione, indicating the probable excretion of As in the pupal exuvia or as a meconium. Results from this study provide valuable information regarding detoxification pathways of As in C. riparius.

Significance of termite mounds in heavy metal exposure.

Frances Duncan[1], Megan Field[2]

[1]University of the Witwatersrand, South Africa, [2]University of the Witwatersrand, South Africa

Many termite species construct large epigeous mounds from the subsoil. Termite mounds have been used in gold exploration as the termites have the ability to transport gold from the subsoil into their mounds. The dome-shaped mounds of Trinervitermes are a prominent feature of the savanna regions of southern Africa. In this study we tested whether during the course of building mounds T. trinervoides were transporting the heavy metal pollutants found in the soil, at two sites near unsealed tailings dams, to their mounds at the surface. Tailings dams, used to store waste generated by gold mining, are a source of heavy metal contamination in soil substrates. A profile of the heavy metal content of two medium sized mounds (30 to 40 cm in height) and the surrounding soil to a depth of 120cm was obtained. The metal content within the different termite castes was also measured. The average heavy metal content of the surface soil layer (0 to 5cm) did not differ significantly from that measured in the mounds. Thus the termite mounds are not bioaccumulating the pollutants. The mounds are built from soil collected from the surface soil layer and not from the subsoil. Thus the heavy metal contamination of the mounds was the same as the surface soil layer. The workers and soldiers appear to be accumulating copper (Cu) and zinc (Zn), however the alates, an important food source for many animals species, had very small amounts of all the metals.

Transgenerational effects of heavy metal exposure on immune defense of the blow fly *Protophormia terraenovae*

Mari Polkki[1], Katariina Kangassalo[2], Markus J. Rantala[3]

[1]University of Turku, Finland, [2]University of Turku, Finland, [3]University of Turku, Finland

Recently environmental conditions during early parental development have been found to have transgenerational effects on immunity and other condition-dependent traits. However, potential transgenerational effects of heavy metal pollution have not previously been studied. Here we show that direct exposure to heavy metal (copper) upregulates the immune system of the blow fly, Protophormia terraenovae, reared in copper contaminated food. In the second experiment, to test transgenerational effects of heavy metal, the parental generation of the P. terraenovae was reared in food supplemented with copper, and the immunocompetence of their offspring, reared in uncontaminated food, was measured. We found that exposure to copper during early parental development stages had the same effect on the immunity of the next generation that was not exposed to heavy metal. Thus, our study suggests that heavy metal pollution has positive feedback effect through generations which multiplies the harmful effects of heavy metal pollution in following generations. Furthermore, our study indicates that changes in immunity will remain in populations even if the environmental conditions have returned to normal and the heavy metal load is no longer apparent. The results of our study suggest that the effect of an environmental toxin in populations might be more complicated than previously thought. This is something which should be considered when evaluating the effects of the pollutants on the viability of animal populations.

An invasive fruit fly benefits from a spatial and behavioural refuge against its introduced egg parasitoid

Katharina Merkel[1], Sunday Ekesi[2], Thomas S. Hoffmeister[3]

[1]University of Bremen, Germany, [2]ICIPE (African Insect Science for Food and Health), Kenya, [3]University of Bremen, Germany

The dynamics of host-parasitoid populations in nature are often strongly influenced by the density dependence in the interaction. Time limited parasitoids are expected to optimize their time allocation across patches often resulting in incomplete host exploitation. Additionally, hosts may create refuges through their spatial distribution, e.g. habitat choice or distribution patterns, or through behavioral and physiological defense mechanisms. We investigated the functional response of Fopius arisanus, an egg-prepupal parasitoid of tephritid flies, on egg masses of Bactrocera invadens at different host densities. The parasitism rate of F. arisanus was inversely density-dependent and followed a Type II functional response. According to Holling's theory the shape of the response results from the time a parasitoid spends handling hosts. Yet, the analysis of our data with Rogers' random-parasite equation revealed that the handling time had a minor - if any - impact on the number of parasitized hosts. Bactrocera invadens lays aggregated egg masses into the fruit pulp such that at higher clutch sizes an increasing number of eggs might be inaccessible for parasitoids. To consider the resulting spatial refuge an exponential refuge term was incorporated into the random-parasite equation. The modified model explained the observed data better than the original model demonstrating that B. invadens benefits from a spatial refuge at higher clutch sizes. As a consequence, the host refuge leads to an inversely density-dependent Type II functional response.

Effects of leaf shape and host larva on oviposition preference of a tachinid fly, Sturmia bella, between two butterfly host plants

Taiki Tsuchida[1], Norio Hirai[2], Minoru Ishii[3]

[1]Osaka Prefecture University, Japan, [2]Osaka Prefecture University, Japan, [3]Osaka Prefecture University, Japan

A parasitoid fly, Sturmia bella (Diptera: Tachinidae), parasitizes more than 20 species of lepidopterans. In this study, oviposition preference and learning ability of the female were examined using Marsdenia tomentosa (Asclepiadaceae, heart-shaped leaf, a food plant of Parantica sita) and Oryza sativa (Poaceae, needle-shaped leaf, a food plant of Parnara guttata) in the laboratory. In the first experiment, we released a naive female fly in a cage with two leaves of both M. tomentosa and O. sativa without any host larvae, and recorded the number of eggs laid on leaves of each plant on the first day (Day 1). On Day 2, we presented M. tomentosa with a P. sita larva and O. sativa without any host larvae in the same way. On Day 3, we presented two plants without any host larvae again. As a result, females laid 90, 92 and 65% of total eggs on O. sativa, M. tomentosa and M. tomentosa on Days 1, 2 and 3, respectively. In the second experiment, we presented two types of paper leaf models, needle-shaped and heart-shaped ones, to naive and conditioned females which experienced a P. sita larva on Day 2 of the first experiment. Naive females laid more eggs (86%) on needle-shaped models than on heart-shaped ones, while conditioned females laid more eggs (86%) on heart-shaped models than on needle-shaped ones. The results show that this species has an ability to learn the leaf shape in connection with existence of the host larva.

Predation on a parasitic fly: Cues arising from the host-parasite interaction increase the predation risk

Sirpa Kaunisto[1], Panu Valimaki[2], Raine Kortet[3], Jani Koskimaki[4], Sauli Harkonen[5], Arja Kaitala[6], Sauli Laaksonen[7], Laura Harkonen[8], Hannu Ylonen[9]

The deer ked (Lipoptena cervi L., Hippoboscidae) is an obligate ectoparasitic fly on cervids. This ectoparasite has expanded its distribution rapidly in Northern Europe during the previous decades. However, the regulating biotic factors such as predation remain unknown for this species. The host-independent pupal stage of the deer ked lasts for several months. Blackish pupae are visible against snow on the bedding sites of hosts, and are thus likely exposed to predators. To evaluate the role of predation on the population dynamics of the deer ked, we monitored pupal predation on experimental bedding sites in three geographical areas in Finland during winter. We explored: (1) possible predators; (2) magnitude of predation; and (3) whether predation risk is affected by cues arising from the host - deer ked interaction, i.e. the snow discoloration. We demonstrate that pupae are predated by a number of tit species. Reddish brown snow discoloration on host bedding sites (indicating heavy infestation of the host) serves as an exploitable cue for avian predators, thus increasing the risk of pupal predation. The ability of tits to use this cue seems to be dependent on the deer ked prevalence on the moose (Alces alces) population and the period of invasion history, which suggests that predation may be a learned behavioural response. Avian predation may thus potentially affect population dynamics of the deer ked locally.

Parasitic wasp learning promotes coexistence with hosts' generation cycles in host-parasitoid system: Neural model analysis

Masakazu Shimada[1], Yumiko Ishii[2], Koji Sasakawa[3], Shin-ichiro Nakayama[4]

[1]University of Tokyo, Japan, [2]National Institute of Environmental Studies, Japan, [3]University of Tokyo, Japan, [4]University of Tokyo, Japan

We have reported the effect of predator learning on coexistence of prey populations using two-host?one-parasitoid experimental systems with two bruchid beetles, Callosobruchus chinensis and C. maculatus as the hosts, and the pteromalid wasp, Anisopteromalus calandrae as their shared parasitoid (Ishii and Shimada, PNAS 2012). When the parasitoid was absent, C.chinensis was competitively excluded in approximately 20 weeks. Introduction of parasitoid greatly enhanced the coexistence time, to a maximum of 118 weeks, where C. maculates and C. chinensis showed periodic anti-phase oscillations. Behavioral experiments confirmed the frequency-dependent predation of A. calandrae, where females of A. calandrae learned the host-related olfactory cues during oviposition and increased their preference for the common host species. We simulated the learning process based on operant conditioning of the parasitic wasp that has a success-experience-reward neural system with neurotransmitters such as octopamine and/or dopamine. The individuals receive information such as which host species to and where to search from the environment. It has a neural system inside and we formulated as cycles based on cognition and behavioral action, consequences from the actions (success, reward or failure), and learning resulting in long-term memory storage. Using the model, we analyzed associative learning with conditioning stimuli (olfactory cue of each bruchid host), frequency-dependent predation of the wasp and the population dynamics with periodic anti-phase oscillations of the two hosts. In addition, we expanded the model for analyzing evolutionary dynamics using Genetic Algorithm for a three-species system with a native, an alien hosts and the wasp.

Endosymbiotic diversity in *Otiorhynchus* spp. (Coleoptera: Curculionidae) - a multitag 454 pyrosequencing approach

Jacqueline Hirsch[1], Stephan Strohmeier[2], Martin Pfannkuchen[3], Annette Reineke[4]

[1]Geisenheim Research Center, Germany, [2]SMS-Development, Germany, [3]Center for Marine Research, Croatia, [4]Geisenheim Research Center, Germany

Worldwide, several members of the weevil genus Otiorhynchus (Coleoptera: Curculionidae) are devastating pests in many horticultural crops. Notching of adult beetles on leaves and flowers as well as larval feeding on roots of their respective host plants may cause serious economic damage. Both nocturnal adult weevils and soil-inhibiting larvae are difficult to control with chemical insecticides or biological control agents. A lot of insects are associated with various endosymbiotic microorganisms and the understanding of their interactions may be used for the development of novel pest management strategies. However, before studying these interactions, a comprehensive picture of the microbial diversity and a detailed phylogeny of selected bacteria present inside the respective insect is required. Here, we used a multitag 454 pyrosequencing approach to assess the bacterial endosymbiont diversity in four different Otiorhynchus species. By sequencing in total ~48,000 PCR amplicons, 49 different operational taxonomic units (OTUs) were identified in the four studied weevil species. In a second step, for a more detailed taxonomic affiliation, specific gene regions of selected OTUs were investigated and a new clade of Rickettsia as well as "Candidatus Nardonella" endosymbionts in Otiorhynchus spp. were identified. As many endosymbionts are involved in manipulation of host reproduction or nutritional relationships, the present results are an important first step in exploring the interactions of bacterial endosymbionts and Otiorhynchus weevils and may be a basis for the development of novel control strategies.

Bracoviruses are symbiotic viruses associated with braconid wasps, which develop within lepidopteran larvae (endoparasitoid). Bracovirus particles are injected into the host with the eggs. The wasps use them to transfer and express virulence genes inside the host. The genome packaged in the particles comprises multiple circular dsDNA molecules, which are produced exclusively in the wasp ovaries from proviral sequences present in the wasp chromosomes. Bracovirus-associated wasps form a monophyletic group and bracoviruses have been chromosomally transmitted from the ancestor of the group. The comparison of bracoviruses proviral genomes gives insights into host/parasite evolutionary dynamics. We have sequenced the proviral segments of Cotesia congregata bracovirus (CcBV) and we have compared them with data obtained previously using two Glyptapanteles species separated from the Cotesia lineage ?17 million years ago. The analyses highlight the stability of the integration sites in the wasp genome identified from conserved hymenopteran genes in the flanking regions of proviral sequences, which contrast sharply with the dynamics of proviral sequences that have undergone large duplications encompassing several segments. To assess how these large genomic changes affect the coding capacity of the bracovirus genome interacting with the host, we measured the non-synonymous versus synonymous substitutions ratio in paired orthologs from four Cotesia bracoviruses (CcBV, CsBV from Kitale, CsBV from Monbassa and C. vestalis BV). This gives new information on the evolutionary arms race occurring between the wasp and its symbiont on one side and the lepidopteran host on the other side.

Cytonuclear interactions and coadaption in a *Trichogramma-Wolbachia* symbiosis

James E Russell[1], Richard Stouthamer[2], Leonard Nunney[3]

[1]Georgia Gwinnett College, U.S.A., [2]University of California, U.S.A., [3]University of California, U.S.A.

The interface between nuclear and cytoplasmic genomes represents the evolutionary arena for some of the most significant biological innovations in the history of life. The cytoplasmic symbiont Wolbachia is perhaps the most widespread bacteria bacterium in the animal kingdom with upwards of 20% of all insects infected. The ability of cytoplasmic Wolbachia bacterial symbionts to influence their nuclear hosts is clear, but the extent to which they coevolve with their host is not clear. We investigated this question using Trichogramma kaykai, a parasitic wasp in which Wolbachia induce parthenogenesis by converting haploid male embryos into diploid homozygous females. We predicted that host-symbiont combinations coevolved in the laboratory for 100 generations would have a higher fitness than novel combinations. By curing infected isofemale cultures, then re-infecting them with Wolbachia from separate cultures, we were able to compare 4 host genotypes and 4 Wolbachia "types" in a factorial design. Our results showed significant host and interaction effects for our 3 fitness variables (total fecundity, offspring sex ratio, and pupal survival) and significant Wolbachia effects on offspring sex ratio. The long-term host-symbiont combinations resulted in 9% increased higher fecundity and 2% higher pupal survival consistent with adaptive coevolution. Looking only at the non-adapted combinations, our results showed significant host effects for all 3 fitness variables (total fecundity, offspring sex ratio, and pupal survival), a significant Wolbachia effect on offspring sex ratio, and significant interaction effects on offspring sex ratio, and pupal survival.

The nest of leafcutter bee *Megachile unbripennis* Smith (Megachilidae) in Bangka Island, Indonesia

Dita Nurtjahya
Gajahmada University, Indonesia

Understanding of the biological role is needed for managing its ecological role and its benefit for human being and ecosystem.Nest construction, building nest duration, plant species, cutting behavior, leaf cutting duration, cutting direction, leaf position and age preference, cut leaf form and area, and cutting time preference from rose leafcutter bee, Megachile unbripennis Smith (Megachilidae) in Sungailiat (Bangka Island) and Yogya (Java Island) were studied. The nest shape of M. unbripenniswas tube, 39 mm length, 8 mm diameter at rear,11 mm diameter in the middle, and 9 mm diameter at the opening. It consisted of 22 - 32 leaf cuts in various sizes between 36 - 223 mm2 with the average of 147 mm2 and was located in the abandoned banana skipper caterpillar's nest, Erionata thrax l. (Hesperiidae). The leaf cuts that constructed the nest werein various sizes depended on their position on the nest. The nest building was relied on season, weather, and temperature.The most suitable season is early until mid dry season or around April - May, bright days, the average rain falls 273 - 181 mm, the average temperature 27oC, and the average of relative humidity is 80.6%. Beside rose leaf (Rosa sp.)(Rosaceae), 13 other plant speciesof 11 families of herbs, shrubs, and trees werecut by the bee. The more frequently cut were on Syzygium polyanthum (Myrtaceae), Bougainvillea spectabilis (Nictaginaceae), and Pterocarpus indicus (Fabaceae).

Comparison of stream macroinvertebrate communities from two Philippine Islands: A biogeographic study

Christine Jewel Cardenas Uy[1], Perry Sim Ong[2], Francis Sebastian Magbanua[3]

[1]University of the Philippines Diliman, Philippines, [2]University of the Philippines Diliman, Philippines, [3]University of the Philippines Diliman, Philippines

Geographical patterns in the distribution of macroinvertebrates were investigated in river systems located in the Mindanao and Leyte Islands. During the late Pleistocene, these two islands were connected and together with Bohol, Samar, DInagat and many other smaller islands form part of the Greater Mindanao Island. Species distribution of mammals, reptiles, amphibians, and freshwater fish provide a strong evidence for the connection of land bridges during the Pleistocene. However, studies testing this connection of Philippine islands using freshwater macroinvertebrates are rare. Consequently, the aim of this study was to investigate if there were differences in the macroinvertebrates community composition between the two islands. Nonparametric multidimensional scaling (nMDS) ordination of samples (macroinvertebrate abundance/site) was performed using Bray?Curtis similarity coefficient. Visual distribution assessment suggested two island biogeographic groups (albeit weak; stress value = 0.19), with a small region of overlap indicating that several taxa are being shared. Nonetheless, differences in macroinvertebrate assemblages were found between islands (ANOSIM R = 0.266, P = 0.002). Of the 75 taxa identified, only 28 (37%) were found in both islands. Further studies integrating molecular phylogenetics and DNA barcodes of stream macroinvertebrates could improve descriptions of community structure and thus provide greater discriminatory ability regarding biogeographic distribution of macroinvertebrates between the two Philippine islands.

Invertebrates mediate the responses of decomposer fungi to elevated temperature

Andrew Donald A'Bear
Cardiff University, United Kingdom

Elevated temperature has potential to influence the biological mechanisms regulating ecosystem-atmosphere carbon exchange. The relationship between warming and heterotrophic microbial respiration remains poorly understood, mainly due to uncertainty regarding the differential sensitivity of microbial groups to temperature and the complexity of interactions with other biota. Grazing soil invertebrates influence the biomass and composition of microbial communities. Cord-forming basidiomycete fungi dominate primary decomposers in temperate woodlands. Warming is expected to stimulate mycelial growth and decomposition, but could also increase the abundance of mycophagous collembola. Increased grazing pressure at elevated temperature is likely to mediate the fungal response to warming. We investigated the impact of elevated temperature on fungal foraging and decomposition of beech (Fagus sylvatica) wood in soil microcosms to which mycophagous collembola were added in factorial combinations with five basidiomycete fungi. Species-specific impacts on mycelial development and function resulted from differential sensitivity of fungi to warming and grazing. Temperature impacts on collembola abundance were resource-specific, causing increased grazing pressure by both species, but on different fungi. When a fungus was palatable to a particular collembola species, increased grazing pressure counteracted warming-induced stimulation of mycelial growth, with implications for colonisation rates of new resources. High grazing pressure did not prevent increased fungal-mediated decomposition of colonised wood, as fungi utilised more resource-derived energy to maintain explorative growth. Impacts of elevated temperature on decomposition are likely to depend on local composition of the fungal and invertebrate decomposer community.

The trial and performance of an international joint study between Korea and Russia for the restoration of Callipogon Relictus

Dae-Am Yi[1], Arkady S. Lelej[2], Andrej K. Kotlyar[3], Alexander V. Kuprin[4]

[1]Yeongwol Insect Museum, Republic of Korea, [2]Biology and Soil Science Institute FEB RAS, Russia, [3]Ussuri reserve FEB RAS, Russia, [4]Ussuri Nature Reserve, Far East Branch, Russian Academy of Sciences, Russia

Center for the Study of Insect Ecology (CSIE, Yeongwol, Korea) entered into a long-term, amicable and mutual agreement for a joint study on Callipogon relictus with FEB RAS (Far East Branch of Russia Academy of Science) in 2006. Callipogon relictus is distributed to the north around North Korea including boundaries of China, boundaries of Russia, especially around Ussuriysk, and to the south around some areas of Gyeonggi-do Province and Gangwon-do province near boundaries between South and North Korea as the southern limit. Callipogon relictus in a large size reaching 8~10cm for the average body length is protected in Russia as it is described in the Red Book, while it is designated as Extinction Crisis Class 1 and our natural monument in Korea. While the population is relatively abundant in Russia, it is considered that it has reached the level of actual extinction in Korea. The first joint study was commenced as a study agreement was entered into between CSIE and Ussurii Reserve in 2007. Both organizations have studied the larval stage of Callipogon relictus without dormancy while breeding larvae of Callipogon relictus respectively in their laboratories. Both organizations adopted the breeding methods in a different way. Ussurii Reserve has seen the emergence of 3 imagoes in 3 years and 8 months in April 2011, as a result of breeding larvae under the conditions of temperature 20 and humidity 60% using raw timber of Ulmus in 50cm length and 60cm diameter since August 2007. On the other hand, CSIE in Korea

Activity of insect fauna during the night, in the palm orchards of central Iraq

Mohammed Zaidan Khalaf
Ministry of Science & Technology, Iraq

The study was carried out at three palm orchards, each of 2.5 hectare in Al-Madain palm orchards(30 km. South Baghdad) contain the palm varieties (Prem, Osta omran, Zahdi , Berhee, Khadrawi , Khastawi ,Oueedi and Tebarzel) in 2010 Season aiming to determination of population density of Palm Borers and to know other insect occurring in Date Palm orchards. Three light traps with solar energy (Magna Traps with lamps of 320 ? 420 nm wavelength are produced by Russell IPM) were used as one trap in each orchard. The number of Fruit Stalk Borer, Oryctes elegans and Frond Borer, Phonapate frontalis adults were calculated per week in each trap aiming to determine the population density of adults in the three orchards under this study. Results of using light Traps (Magna Traps) indicated that the number of O. elegans adults catch per trap during the period from April to December 2010 were 254 , 217 and 240 adult per trap in orchards No. 1, 2 and 3 respectively , the higher population densities were 87 ,79 and 81 adult /trap per month, respectively reported in July. Also, The study indicated that the population density of Frond Borer, Phonapate frontalis catch per Trap during the period from April to December 2010 were 34, 58 and 54 adult /trap for orchards No. 1, 2 and 3 respectively, The higher population densities were 10, 21 and 15 adult/trap per month, respectively reported in June.

Comparative studies of behaviourial variations of *Apis mellifera* L. species in Nigeria

Akeem Abolade Oyerinde[1], Micheal Chidozie Dike[2], Lucius Joseph Bamaiyi[3], Rabiu Saliu Adamu[4]

[1]University of Abuja, Nigeria, [2]Ahmadu Bello University, Nigeria, [3]Ahmadu Bello University, Nigeria, [4]Ahmadu Bello University, Nigeria

230 words Studies were conducted for three beekeeping seasons (between 2009 and 2011) on 400 colonized hives sited in the two major vegetation zones of Nigeria. Direct counting of the number of sting babels deposited on the beekeepers kit by scout bees defending her colony was done during the period of routing inspection and harvesting of crops from selected colonies while swarming and abscondment of established colonies after the first visit was noted and recorded for each farm. Behaviourial variations of Apis mellifera species from the forest and savannah vegetation zones of Nigeria revealed that majority (above 65%) of the honeybees were highly aggressive and none of the colonies in the country was stingless. The preponderance of the deposit of the sting babels by the scout bees in the nation was highly aggressive +++> aggressive ++ > less aggressive + >stinglessness ?. Comparison of behaviourial variations of Apis mellifera colonies in Nigeria revealed that Abuja (31.3%), Adamawa (4.0%) and Osun (3.3%) States had the less aggressive species of honeybees while, both Kebbi (80.7%) and Ebonyi (79.7%) States recorded the highest percentages of sting babels deposition in the savannah and forest vegetation respectively. The percentage of abscondment and swarming

Circadian control of oviposition and hatching in *Epilachna vigintioctopunctata* (Coloeoptera: Coccinellidae): A laboratory study

Navodita George Maurice
Shiats, India

The ladybird beetle belongs to the family Coccinellidae of order Coleoptera. The members of the family are solely predator on aphids, mealybugs, scale-insects, whiteflies, thrips, leafhoppers, mites and other small soft bodied insect pests. It is known to prey on about 39 arthropod species. The predatory coccinellids occupy all the habitats and niches of their preys and are dispensed worldwide. Epilachninae a subfamily of Coccinellidae is exemplified by existence of phytophagous species which are pests of imperative agricultural crops and their range widens throughout India, Pakistan, China, Japan, Southeast Asia and Oceania. The members bear close semblance in size, appearance, overlapping distribution and equivalent food habits so are deemed as cost-effectively significant beetle pests. Epilachna vigintioctopunctata (Fabricius) recurrently recognized as the 28-spotted ladybeetle or the hadda beetle is a very frequent pest of nightshades and cucurbits. The nature of damage varies with the geographical regions where both the adults and the grubs are accountable for declination of the crop yield. Normally the crest is found in July and August. Both adult beetles and grubs feed on the epidermal tissues by scrapping, ensuing drying up and falling of the leaves due to which they are sometimes called leaf scrapping coccinellid beetles. The study also spotlights that food plays a momentous effect on oviposition and age of female also casts its spell on oviposition. Oviposition was found to augment as age of female amplifies, attains its crest and then ultimately declines.

Distributions and seasonal fluctuations of carabid species (Coleoptera: Carabidae) of hazelnut plantations in Turkey

Gregory Thomas Sullivan[1], Sebahat K. Ozman-Sullivan[2], Memis Kesdek [3]

[1]Ondokuz Mayis University, Turkey, [2]Ondokuz Mayis University, Samsun, Turkey, [3]Mugla University, Turkey

The family Carabidae, or ground beetles, is one of the largest families of Coleoptera. They are important natural enemies in agroecosystems. There are approximately 600,000 ha of hazelnut plantations in Turkey that usually feature continuous groundcover and minimal disturbance by machinery. Pitfall traps were established in June 2011 at 17 sites along the eastern Black Sea coast from Samsun Province to Trabzon Province. Trapping ranges over a distance of 350 km from east to west and to 450m altitude. The three traps at each site were checked every 2 weeks in spring, summer and autumn and 3-4 weeks in winter. To date, 32 species from 15 genera have been collected. Pseudoophonus rufipes was the most common and widely distributed species, following by Brachinus explodens. From the well known predatory genus Carabus, C. chevrolati chevrolati, C. wiedemanni anceps and Carabus spinolae salignus were the most common. Carabus (Procrustes) chevrolati chevrolati was the most widely distributed species. Carabus robustus triumphans and Carabus bonvouloiri bonvouloiri, an endangered species, were also collected. Numbers of species and their distributions varied considerably from site to site, including altitude, and abundance was greatest in summer and autumn. Some species continued to be active during warm winter weather.

Effects of the host plant on the biology and life-table parameters of two-spotted spider mite

Mona Maghsoodlou[1], Mohammad Mohsen Montazeri[2], Hajar Pakyari[3]

[1]Gorgan branch, Islamic azad university, Iran, [2]Gorgan branch, Islamic azad university, Iran, [3]Faculty of agticulture, Islamic azad university, Takestan branch, Iran

Studies on the biology and life-table parameters of two-spotted spider mite, Tetranychus urticae Koch on three leguminous hosts, Common bean, Phaseolus vulgaris, Vetch Vicia sativa and Soybean Glycine soja revealed indicated that the duration of different developmental stages of T. urticae were 3.94, 2.69 and 2.93 days for eggs, 1.26, 2.1 and 1.96 days for larvae and 2.22, 3.38 and 2.67days for nymph, respectively. The fecundity were 23.04, 35.63 and 33.92, eggs/female, while pre-oviposition, oviposition and post-oviposition periods lasted for 2.89, 3.62 and 0.21 days on common bean, 1, 4.13 and 0.59 days on vetch 0.7, 3.80 and 0.4 days on soybean, respectively. The total developmental period from egg to adult was recorded as 7.42,7.56 and8.17 days and longevity of male were 4.71, 4.17and 3.55 days and that of female were 5.76, 4.9 and 3.94 days. Demographic parameters (Ro, rm , λ ,T and DT) of T. urticae were 8.523, 0.178, 1.194, 12.065 and 3.903 on common bean, 4.456,0.159,1.163, 9.885 and 4.587 on Vetch and 6.783, 0.209,1.233, 9.158 and 3.316 on Soybean.

Heritable variation of life-history traits in an adapted spruce budworm population

Roberto Quezada Garcia[1], Eric Bauce[2]

[1]*Universite Laval, Canada,* [2]*Universite Laval, Canada*

The spruce budworm is a major pest in the boreal forest of North America; this native insect exhibits eruptive behaviour in approximately 30-year cycles. There is no explanation of what causes the populations in the forest to rise and fall; it could be due to coevolution processes. There are two components involved in adaptive evolution: natural selection acting on the phenotype, and genetic variability in phenotypic traits. The integration of these components may provide information about causes and constraints on evolution in contemporary populations. Understanding heritability in the spruce budworm could be key to answering fundamental questions about its adaptation. The purpose of this study was to estimate the heritability of life-history and metric traits in the spruce budworm. To avoid environmental variability, budworms were reared on an artificial diet and under laboratory conditions. We estimated heritability by parent-offspring regression analysis of the following traits: fecundity, egg fertility, developmental time, and pupal mass weight. Results indicate that the population maintains substantial additive variance in life-history traits like other groups of Lepidoptera, and low heritability in pupal mass weight. This suggests that natural selection on spruce budworm is probably higher during the winter period. This information is very useful in predicting heritable variation under epidemic conditions.

A test of genetic theories underlying Haldane's Rule with haplodiploid wasps

Tosca Koevoets[1], Louis van de Zande[2], Leo W. Beukeboom[3]

[1]University of Groningen, Netherlands, [2]University of Groningen, Netherlands, [3]University of Groningen, Netherlands

Haldane's Rule describes a pattern early during speciation in which the hetero(hemi)gametic sex suffers stronger from hybridization than the homogametic sex. Three main genetic theories try to explain Haldane's Rule: the dominance, the faster-male and the faster-X theory. The question is whether the hetero(hemi)gametic sex is more susceptible to hybrid incompatibilities due to its sex or its hemizygosity of the sex chromosome. We show how haplodiploid organisms (haploid males, diploid females) are uniquely suited for studying the genetic basis of Haldane's Rule. We constructed sex-reversed diploid males of the haplodiploid wasp Nasonia vitripennis and compared their levels of hybrid incompatibilities with haploid males and diploid females. Inviability and sterility was low in diploid males and females compared to haploid males indicating the absence of sex-specific incompatibilities. Genomic regions associated with hybrid mortality were similar in diploid males and females, but less frequent than in haploid males. Dominance effects were found in some regions, but homozygosity of incompatible loci was mostly rescued by diploidy in hybrid males and females. Dosage effects of incompatibilities is a novel phenomenon for explaining Haldane's Rule. It may be specific for haplodiploids, but could also apply to X-linked incompatibilities in diploid species.

Joining forces in defense: Production dynamics of symbiont-mediated antibiotics reveal long term antimicrobial protection for wasp offspring

Sabrina Koehler[1], Martin Kaltenpoth[2]

[1]Max-Planck-Institute for Chemical Ecology, Germany, [2]Max-Planck-Institute for Chemical Ecology, Germany

Bacteria-produced antibiotics play a pivotal role in pharmacology to treat a plethora of microbial infections. Recently, insects have also been found to benefit from these antimicrobial properties to defend the host or its nutritional resources against pathogens. In the solitary digger wasp Philanthus triangulum, a cocktail of nine different antibiotics, produced by Streptomyces symbionts, inhibits the growth of detrimental microorganisms and significantly enhances the offspring´s survival probability. Using GC-MS and RT-qPCR we investigated the dynamics of antibiotic production during beewolf development. The analyses revealed a relatively constant Streptomyces population size over time. By contrast, we found a significant change in the antibiotic amount, with a strong increase of antibiotics within the first two weeks after cocoon spinning, and a slow subsequent decrease, indicating that antibiotic production is optimized to serve as a reliable long term protection during the unpredictable developmental phase of beewolf larvae.

Predation selects for lower resting metabolic rates in *Tenebrio molitor*

Indrikis Krams[1], Tatjana Krama[2], Janina Daukste[3], Inese Kivleniece[4], Markus J. Rantala[5]

[1]University of Daugavpils, Latvia, [2]University of Daugavpils, Latvia, [3]University of Daugavpils, Latvia, [4]University of Daugavpils, Latvia, [5]University of Turku, Finland

The energetic definition of fitness predicts that natural selection will maximize the residual energy available for growth and reproduction, suggesting that energy metabolism might be a target of selection. In this experimental study we investigated whether female and male yellow mealworm beetles (Tenebrio molitor) differ in their hiding behaviour, individual response latency time, and duration of immobility to treatments mimicking an approaching predatory threat. We experimentally tested whether consistently repeatable anti-predatory responses and resting metabolic rates (RMR) correlated with survival rates of individuals exposed to a nocturnal predator, the Norwegian rat (Rattus norvegicus). RMR was part of a complex syndrome involving anti-predator behavior. Individuals with lower RMR concealed themselves against predators in the layer of bran more often than individuals with higher RMR, and hiding was associated with longer periods of immobility. Our results provide direct evidence of natural selection against elevated RMR in T.molitor beetles.

Temperature-dependent, behavioral, and transcriptional variability of a tritrophic interaction consisting of bean, herbivorous mite, and predator

Gen-ichiro Arimura[1], Rika Ozawa[2], Osamu Nishimura[3], Shigenobu Yazawa[4], Junji Takabayashi[5]

[1]Kyoto University, Japan, [2]Kyoto University, Japan, [3]Kyoto University, Japan, [4]Kyoto University, Japan, [5]Kyoto University, Japan

Different organisms compensate for, and adapt to, environmental changes in different ways, and therefore environmental changes affect animal?plant interactions. We assessed the effect of temperature on a tritrophic system consisting of the lima bean, the spider mite Tetranychus urticae, and the predatory mite Phytoseiulus persimilis. In this system the plant defends against T. urticae by emitting volatiles that attract the predatory mite P. persimilis. Over a temperature range of 20°C to 40°C the emission of volatiles by infested plants, and the attraction of P. persimilis, peaked at 30°C but the number of eggs laid by T. urticae adults, and the number of eggs consumed by P. persimilis, peaked at 35°C. This finding indicates that the temperature at which both spider mites and predatory mites performed optimally was higher than the temperature at which the volatile attractants were produced at the greatest levels. We used data from transcriptome pyrosequencing of the mites and found that P. persimilis up-regulated gene families for heat shock proteins (HSPs) and ubiquitin-associated proteins, whereas T. urticae did not. RNA interference-mediated gene suppression in P. persimilis, developed in the current study, revealed that the strongly induced PpHsp70-1 contributed to the predation of T. urticae eggs at 35°C but not at 25° C. Overall, our molecular and behavioral approaches revealed that the mode/tolerance of lima bean, T. urticae, the predatory mite P. persimilis are distinctly affected by temperature variability, thereby causing temperature-dependent, mutualisms in the tritrophic level.

Biology of coconut black-headed caterpillar, *Opisina arenosella* Walker (Lepidoptera: Oecophoridae), records of alternative host plant and its natural enemies in Thailand

Namphueng Chomphukhiao[1], Wiwat Suasaard[2], Sopon Uraichuen[3], Oraphan Kernasa[4], Paweena Buchatian[5]

[1]National Biological Control Research Center (NBCRC), Thailand, [2]Agricultural at Kamphaeng Saen, Kasetsart University Kamphaeng Saen Campus, Thailand, [3]Agricultural at Kamphaeng Saen, Kasetsart University Kamphaeng Saen Campus, Thailand, [4]Agricultural at Kamphaeng Saen, Kasetsart University Kamphaeng Saen Campus, Thailand, [5]National Biological Control Research Center (NBCRC), Thailand

Due to the devastating outbreak of the black-headed caterpillar, Opisina arenosella Walker in Southern Thailand in 2010, gathering the information of the pest insect is essential. Accordingly the insects were reared on their alternative host plant, banana leaves, to study their biology. Female adults laid yellowish creamy color eggs in mass. The newly hatched larva was orange-red and then turned to pale yellow, with dark brown head. Three brown lines ran along the lengthwise of the body. Thorax color was paler than that in head and legs. The oval shape pupae were dark brown. Head, antennae, wings and abdomen of adult were light gray. Female was larger than males. Average number of egg laid was 83.40±14.31 /female until death. Egg duration averaged 4.90±0.55 days. Larvae of O. arenosella had 10 to 13 instars with a larval period 57.67±9.25 days. The pupal period was 9.08±0.90 days. Longevity of male and female were 10.33±5.01 and 9.00±1.22 days, respectively. Mean duration life cycle was 80.45±10.46 days. Further study on alternative host plants of O. arenosella in Nakhon Pathom and Prachuap Khiri Khan provinces, Thailand from November 2010 to August 2011, disclosed a total of 11 species; 10 species of Palmae and one species of Musaceae. Additionally, five species of parasitoids (Hymenoptera: Braconidae, Chalcididae, Eupelmidae, Eurytomidae and Eulophidae) and two of insect predators (Hemiptera: Pentatomidae; Dermaptera: Chelisochidae) were collected in the outbreak areas.

Slow-growth-intraguild predation- status; when the diet determines your IGP status...

Eric Lucas
Universite du Quebec a Montreal, Canada

The slow-growth-High-mortality hypothesis states that organisms with a slower development will suffer a higher mortality than organisms with a shorter development. Omnivorous natural enemies can exploit an array of different food sources, from animal and plant material. These food sources being of different qualities would affect the growth, development, vigor and survival of the insects. More specifically, a low-quality diet will extend the larval developmental time, and at a specific time have produced smaller individuals. Consequently, we formulated the hypothesis that, in an intraguild interaction context, the diet will determine the IGP status of the focal natural enemies. We predict that individuals fed with a high-quality diet will be more often intraguild predators than individuals fed with a low-quality diet. We worked with two north-American ladybeetle species at the larval stage. The twelve-spotted ladybeetle was fed either on a high or low-quality diet and confronted to the Asiatic ladybeetle. Results will be discussed considering priority factors and overwintering behaviors.

Evolution of cooperation: Insights from a tiny haplodiploid insect.

James David Jensen Gilbert[1], Stephen J. Simpson[2]

[1]University of Sydney, Australia, [2]University of Sydney, Australia

Cooperation in nature is a paradox for behavioural ecologists, who interpret most behaviour as fundamentally selfish. Species that can choose whether or not to cooperate are especially helpful in understanding how this behaviour evolved. Tiny female Acacia thrips (Dunatothrips aneurae) often cooperate to build nests from tied phyllodes of mulga (Acacia aneura). But this carries a cost: cooperating females get fewer offspring than solitary females. Evolutionary logic suggests there must be a benefit to counterbalance this cost. Cooperation in thrips is especially interesting because they are haplodiploid, and so represent a genetic parallel to similar well-studied systems in the Hymenoptera. However, very little is currently known about the basic natural history of this species. We explore the natural history and cooperative behaviour of D. aneurae in the field and lab. D. aneurae domiciles were highly patchily aggregated. The thrips showed no aggression of any kind. Invading inquiline thrips disrupted reproduction by competing for resources within domiciles. Mating among nestmates was common. Females required male presence to initiate domiciles. Cooperation was more readily induced simultaneously than by females joining nests sequentially. Larger nests contained middens of discarded waste. Cooperation was associated with (i) higher per capita survival, (ii) a narrower range of phyllode dimensions in domiciles, (iii) local crowding and/or east-facing orientation on trees, (iv) reduced hydroxyproline in phyllodes, indicating reduced drought stress. D. aneurae and its domicile-building congeners promise to become an interesting new model clade for asking questions about how and why cooperation evolved.

Winter host selection influences fitness traits in an aphid parasitoid

Thiago Oliveira Andrade[1], Maxime Herve[2], Yannick Outreman[3], Liliane Krespi[4], Joan van Baaren[5]

[1]Universite de Rennes 1, France, [2]Universite de Rennes 1, France, [3]Agrocampus Ouest, France, [4]Universite de Rennes 1, France, [5]Universite de Rennes 1, France

Organisms can either evade winter's unfavourable conditions by migrating or diapausing, or endure them by maintaining their activities. When it comes to foraging during winter, a period of scarce resources, there is a strong selective pressure on resource exploitation strategy. Generalist parasitoids are particularly affected by this environmental constraint, as their fitness is deeply linked to the profitability of the chosen hosts. In this study, we considered a cereal aphid-parasitoid system and investigated (i) the host-parasitoid community structure, host availability and parasitism rate in winter, (ii) the influence of host quality in terms of species and instars on the fitness of the aphid parasitoid Aphidius rhopalosiphi, and (iii) whether host switching has an impact on parasitism success for that parasitoid species. Host density was low during winter and the aphid community consisted of the species Rhopalosiphum padi and Sitobion avenae, both parasitized by A. rhopalosiphi at non-negligeable rates. A. rhopalosiphi produced offspring more often when parasitizing R. padi when compared to S. avenae, but the latter aphid species originated significantly bigger parasitoid offspring. Though aphid adults and old larvae were significantly larger than young larvae, these last ones resulted in both higher emergence rates and larger parasitoids. Host switching did not bear any detectable negative consequences on parasitoid emergence rates or offspring body size. This study provides some evidence that winter A. rhopalosiphi populations are able to take advantage of a large array of host types that vary in profitability, indicating that host electivity drops under winter's unfavourable conditions.

Effect of mating interactions between females and males from different primary host species on host feeding and parasitism by the autoparasitoid *Encarsia sophia*

Liansheng Zang[1], Changchun Ruan[2], Fanghao Wan[3]

[1]Institute of Biological Control, China, [2]Institute of Biological Control, China, [3]Key Laboratory for Biology of Plant Disease and Insect Pests, Institute of Plant Protection, China

The autoparasitoid Encarsia sophia not only parasitize whiteflies but also kill them with strong host-feeding capacity. In this study, E. sophia females and males were reared on primary hosts, Trialeurodes vaporariorum and Bemisia tabaci 'Q', and the host-feeding and parasitism of wasps on both whitefly species were determined in all different mating combinations: (i) E. sophia female reared on B. tabaci (ESF-BT) mated with E. sophia male from B. tabaci (ESM-BT), (ii) E. sophia female reared on T. vaporariorum (ESF-TV) mated with E. sophia male from T. vaporariorum (ESM-TV), (iii) ESF-BT mated with ESM-TV, (iv) ESF-TV mated with ESM-BT. ESF-TV mated with ESM-TV killed most whitefly nymphs of B. tabaci and T. vaporariorum through host feeding. The larger ESF-TV in body size mated with larger ESM-TV killed more whitefly nymphs through host feeding than those mated with smaller ESM-BT. Whether B. tabaci or T. vaporariorum were used as hosts, ESF-TV mated with ESM-TV and ESM-BT, and ESF-BT mated with ESM-TV significantly parasitized more whitefly nymphs than ESF-BT mated with ESM-TV. In general, the mating combination of female and male originated from T. vaporariorum caused largest mortality of whitefly through parasitism and host feeding on both whitefly species, but the combination of ESF-BT mated with ESM-TV killed fewest whiteflies. These results indicated that the performance of autoparasitoids on insect pests was not only dependent on females, but also affected by mating males from different primary host species.

Morphological changes correlated with horsehair worm infection in *Hierodula formosana* Giglio-Tos (Mantodea: Mantidae)

Ming-Chung Chiu[1], Chin-Gi Huang[2], Wen-Jer Wu[3], Shiuh-Feng Shiao[4]

[1]National Taiwan University, Taiwan, [2]National Taiwan University, Taiwan, [3]National Taiwan University, Taiwan, [4]National Taiwan University, Taiwan

Parasitism is a strong driving force of evolution for both hosts and parasites. This long-term coevolution usually causes unusual phenotypes in the infected hosts. Parasite-correlated alterations of host morphology have been recorded in many host-parasite associations. Since the morphology reflects the development and the selective pressure within a given environment, it is also a good index to know the strategy of both parasites and hosts. Hierodula formosana is a common mantid species in Taiwan, and their adults are always found to harbor the parasitic horsehair worms, Chordodes formosanus. In this study, we compared the external morphology of Hierodula formosana, including both sexes and infected individuals. The infected mantids were found to have smaller body sizes and the relatively shorter wings. Additionally, shorter mid legs and hind legs, and lower density of antennal sensilla were also found on the infected males. In conclusion, allometry in the mantid hosts somehow implied the decrease in locomotion ability as well as the interference in development by parasites. As the reduced number of antennal sensilla happened in our infected mantid hosts was also found in some juvenile insects like cockroaches, we also believe this probable parasite-induced juvenilization may have widely appeared in many parasitism cases to avoid adults investing too much energy in dispersal and reproduction.

Ecological plasticity and genetic diversity of the mango blossom gall midge, *Procontarinia mangiferae* (Felt), in Reunion Island

Paul Amouroux[1], Frederic Normand[2], Samuel Nibouche[3], Helene Delatte[4]
[1]CIRAD, France, [2]CIRAD, France, [3]CIRAD, France, [4]CIRAD, France

Phytophagous insects that belong to the Cecidomyiidae family are among the most closely associated with their host plants. Phytophagous insects can specialize not only on a unique host plant but on particular parts of plants as well. Mango blossom gall midge, Procontarinia mangiferae, is a mango pest that causes damage to both inflorescences and leaves. The objectives of our study were to highlight the genetic diversity and ecological abilities of a monophagous gall midge and to evaluate the determinants of its genetic structure in subtropical Reunion Island. This study, carried out on an isolated island, is based on morphological and molecular data (mitochondrial DNA and microsatellites). Using mitochondrial COI gene sequences, polymorphism at 11 microsatellite loci and an extensive sampling of 27 populations at 17 sites, we tested the genetic differentiation between populations sampled on different mango organs, different mango cultivars and at different seasons. Our results showed that a single species, P. mangiferae, was present all year round at all of the sites sampled, regardless of climatic and cultural conditions, and that it fed on both inflorescences and young leaves. Moreover, our study highlighted the ecological plasticity of this species. However, unlike previous studies on other Cecidomyiidae species, the population genetic structure did not appear to be determined by the species' ability to feed on different organs of the same host plant, but rather by the geographical distribution of populations.

Are sneaky males making the best of a bad lot or reaping the rewards? Alternative reproductive tactics in the giraffe weevil (*Lasiorhynchus barbicornis*).

Christina Painting[1], Thomas R. Buckley[2], Gregory I. Holwell[3]

[1]University of Auckland, New Zealand, [2]Landcare Research, New Zealand, [3]University of Auckland, New Zealand

Many animal species have evolved weaponry as a means to resolve conflict between conspecifics in the acquisition of mates. Males with the largest weapon or body size are generally thought to have a competitive advantage during conflict. However, in some species where there is high adult size variation, small males employ alternative reproductive tactics (ARTs) that do not rely on weaponry to gain access to females for copulation. These tactics are often in the form of sneaking by small males, versus guarding by large males. Despite these ARTs, subordinate males are usually thought to have a lower mating success than dominant males, and are simply "making the best of a bad lot". Males of the giraffe weevil (Lasiorhnychus barbicornis) (Coleoptera: Brentidae) have an elongated rostrum which is used as a weapon to compete with other males to secure females for copulation. However, males are also highly size variable such that there is a 6-fold difference between the smallest and largest equivalent-aged individuals. We found that small males, in addition to using their rostrum to fight, will also use sneaking tactics to copulate with females while larger males stand guard. To determine if body size is a determinant of mating success, and to investigate the influence of both seasonal and local density on the relative mating success of different sized individuals, we conducted an extensive series of field-based observations between 2010 and 2012. These results will be discussed in the context of sexual selection, competition, and alternative reproductive tactics.

Gall formation strategies of *Idarnes* group *flavicollis* associated to *Ficus citrifolia* in Brazil

Sergio Jansen[1], Simone Padua Teixeira[2], Rodrigo A. Santinelo Pereira[3]

[1]Universidade de Sao Paulo, Brazil, [2]Universidade de Sao Paulo, Brazil, [3]Universidade de Sao Paulo, Brazil

We studied the galling process of a non-pollinating fig wasp species Idarnes group flavicollis associated to Ficus citrifolia in Brazil in both pollinated and unpollinated figs between 2010 and 2011. For pollinated treatment, simultaneous to wasp oviposition we injected a sucrose 5% solution with pollen through the fig ostiole. We conducted pollinated and unpollinated treatments in two and three F. citrifolia trees, respectively. From oviposition day we sampled 4-5 figs each two days until larva completed development. For each sample, we dissected 20 randomly-picked galls; we measured larva total body length and recorded its position inside the gall. We also destined 10-20 developing galls and seeds at four-day intervals for histological study. Female deposits its egg between ovule inner integument and nucellus. First larval stage (0.206±0.059mm, n=60) begins to feed on hypertrophied nucellus. In pollinated oviposited flowers, endosperm and plant embryo cells suffered hypertrophy which interrupted its normal development. Larva position changed in second larval stage (0.745±0.207mm, n=60) to the micropillar region. Second larval stage fed on hypertrophied cells originated from either nucellus or endosperm/embryo. Third larval stage (1.507±0.291mm, n=80) continued to grow until it occupied the whole gall cavity. We show that although this Idarnes species oviposits at a same fig developmental stage as the pollinator and emulates the location where pollinator's egg is deposited, galling strategies differed considerably from it. Successful gall formation in Idarnes group flavicollis is independent from plant fertilization. Financial support: S.J.G. FAPESP#09/10237-9. R.A.S.P. FAPESP#04/10299-4 and CNPq#302769/2008-0. S.P.T. Does overheating risk affect the evolution of cryptic coloration?

Kaori Tsurui[1], Takayoshi Nishida[2]

[1]Hirosaki University, Japan, [2]The University of Shiga Prefecture, Japan

Cryptic coloration has multiple functions, such as thermoregulation and /or signaling, which are potentially incompatible each other. Here we focus on rarely explored trade-offs between camouflage and thermoregulation. A polymorphic pygmy grasshopper Tetrix japonica exhibits male-limited absence of black markings, despite of their enhanced camouflage effect. The grasshopper males search for females under strong sunlight in summer. According to the thermal melanism theory, ectothermic melanistic individuals get warm and reach higher equilibrium temperatures faster than lighter ones. Therefore, the black markings of the grasshopper males are expected to incur the overheating risk. We hypothesized that the non-marked males took an overheating avoidance strategy. Choice experiments for radiation heat in the laboratory revealed that non-marked males stay longer under radiation heat than marked males did, though the body temperature of the two morphs was quite similar when they started to hide from the radiation heat. These results suggested that non-marked males got less warm and could stay longer for mate searching than marked males did. Namely, non-marked males were advantageous in hot conditions. This was strongly supported by the altitudinal and latitudinal clines, respectively at regional and geographic scales, with greater proportion of the non-marked males in lower and southern areas.

Plastic defensive behavior of termite workers depending on social context

Yuki Ishikawa[1], Kei Tanabe[2], Hitoshi Aonuma[3], Toru Miura[4]

[1]Tohoku University, Japan, [2]Hokkaido University, Japan, [3]Hokkaido University, Japan, [4]Hokkaido University, Japan

Social insect colonies are self-organized systems that flexibly respond to environmental changes such as a single organism. By altering the caste proportions, social insects change the task allocation according to colony demands. In this sense, the differentiation of termite soldiers, which are morphologically specialized to colony defense, is regulated depending upon requirements like caste proportion of colonies. However, the soldier differentiation from larvae (or workers) requires a relatively long time to be accomplished. To achieve flexible and emergent colony defense, other rapid-response mechanisms can be predicted. To test our prediction, we quantified the defensive responses of soldiers, pseudergates (workers) and reproductives of the damp-wood termite Hodotermopsis sjostedti. When the isolated castes were exposed to an intruder, soldiers exhibited the most vigorous defensive response, followed by pseudergates and then reproductives. Under paired condition, while the aggression levels of soldiers and reproductives were independent of the accompanying castes, pseudergate aggression was more plastic and depended on the other castes present. When paired with reproductives, pseudergates exhibited high levels of aggression towards enemies, while the pseudergate aggression remained low when they were paired with soldiers. The results indicate that pseudergates modulate their defensive response depending on social context, possibly contributing rapid and flexible responses required for colony defense. To elucidate the underlying physiological mechanisms, we further investigated the contributions of biogenic amines on the defensive behavior of pseudergates. The results suggest that tyraminergic/octopaminergic systems regulate the aggression levels of pseudergates, indicating the possible regulatory roles in the social defensive responses of termite colonies.

Age-related male reproductive investment and female fitness consequences in a moth, *Ostrinia scapulalis*

Aye Thanda Win[1], Wataru Kojima[2], Yukio Ishikawa[3]

[1]The University of Tokyo, Japan, [2]The University of Tokyo, Japan, [3]The University of Tokyo, Japan

Energy spent on current reproduction could reduce the potential for future reproduction since energy is a limited resource. According to the terminal investment hypothesis, costly reproductive investments should be increased toward the end of a lifespan when the probability of reproduction and survival becomes low. We investigated age-related changes in male reproductive investment toward courtship display and the spermatophore in a monandry moth, Ostrinia scapulalis. We found that older males had higher mating success than younger males under both choice and no-choice conditions. Observations of behavior in the two-choice (1- and 3-day-old male) test revealed that older (3-day) males courted more frequently than younger (1-day) males, but there was no difference in rejection rates of between the two groups. These results indicate that the higher mating success of older males is attributable to the increased frequency of courtship display rather than a female preference for older males. Moreover, we found that older males produced a larger spermatophore containing more protein than younger males. Older males copulated for a longer period of time than younger males, which probably contributed to the transfer of a larger spermatophore. Although age-related resource allocation in courtship and spermatophore production was consistent with the terminal investment hypothesis, male age did not affect female fecundity and longevity. Deterioration of sperm in the older males might counteract the nutritional benefit of larger spermatophores. Alternatively, fitness components other than longevity and fecundity may be influenced by male age.

Finding signatures of selection imposed on insect by urbanization

Sergei Lysenkov[1], Peter Chang[2]

[1]Moscow State University, Russia, [2]University of Southern California, U.S.A.

The process of urbanization is hypothesized to be a new source of selection on the life beings dwelling human-transformed habitats. To test this idea we have chosen two insect species: black garden ant Lasius niger (Hymenoptera: Formicidae) and common house mosquito Culex pipiens (Diptera: Culicidae). Populations of these species from the urban and natural habitat in the same region were sequenced and compared to find the signatures of selection acting on these insects in urban environment. Ant samples are from Moscow region (Russia), and mosquitoes ? from Moscow and Tula region (Russia). Urban samples came from Moscow which is a great megapolis, and from the small industrial town Aleksin (in Tula region) which is less urbanized than Moscow. The natural populations for the comparison were sampled in the rural areas near these cities. The results of the sequencing and theur bioinformatic analysis is upcoming this summer.

Mating experience weakens starvation tolerance in the seed bug *Togo hemipterus* (Heteroptera: Lygaeidae)

Chihiro Himuro[1], Kenji Fujisaki[2]

[1]*Laboratory of Evolutionary Ecology, Okayama University, Japan,* [2]*Kyoto University, Japan*

Organisms are exposed to various stresses caused by environmental fluctuations. One of the most common stresses is the shortage of food. Individuals of many species must survive periods of starvation. There appears to be a trade-off between reproduction and survival. When residual reproductive value declines for an individual, life-history theory predicts an increase in current reproductive investment. Current reproductive investment differs between virgin and mated individuals. It is likely that mating experience influences starvation tolerance. However, few studies have investigated sex differences in the effect of mating experience on starvation tolerance or clarified the causes of reductions in starvation tolerance in both sexes. In the present study, these questions were investigated using the seed bug Togo hemipterus (Heteroptera: Lygaeidae).The results of the present study demonstrated that mating is costly for both sexes. Mated males showed very short survival times and a daily reduction in weight, and daily energy expenditures were significantly greater in mated males than in virgin males. It is possible that starvation increases the mating effort of males, such as behavioural activities and the amount of time spent searching for females. A trade-off between survival duration and lifetime fecundity was found in virgin females. However, there was no trade-off in mated females, which had very short survival times. Whether male seminal substances contribute to the short survival times of mated females was considered. This is the first report demonstrating the influence of sex and mating experience on starvation tolerance. Sex-specific causes for reductions in starvation tolerance are discussed.

Overwintering Adults of *Danaus genutia* (Lepidoptera, Nymphalidae: Danainae) in South-central Yunnan are in quiescence

Chengli Zhou[1], Zhen Chen[2], Xiaoming Chen[3]

[1]Research institute of resource insects, Chinese academy of forestry, China, [2]Research institute of resource insects, Chinese academy of forestry, China, [3]Research institute of resource insects, Chinese academy of forestry, China

Adults of the common tiger butterfly, Danaus genutia Cramer (Lepidoptera, Nymphalidae: Danainae), can be seen all the year round in the river valleys in Yuanjiang county, south-central Yunnan province. The frequency of mated females in the natural population dropped dramatically from early September to middle December with oviposition ceased gradually within this period. From middle November to mid December, no female was found to contain mature oocytes and all males contained undeveloped spermaries. When hold in 27.5℃ (LD16:8) for 10-30 d, 95%-100% of females (n = 15-20) had mature oocytes and all males (n = 35) had developed spermaries. In the laboratory experiments, all females and males kept in 17.5℃ from eclosion had undeveloped ovaries or spermaries, regardless the conditions experienced during larval and pupal stages. After transferred to 25℃ for 10 d, all adults developed mature ovaries or spermaries, with most females containing mature oocytes. The results indicate the reproductive dormancy in overwintering adults is a state of quiescence. We suggest the few (3.45%, n = 58) diapausing females detected might be migrants from the northern distributions.

Characterization of overwintering sites of brown marmorated stink bug (Hemiptera: Pentatomidae) in natural landscape

Doo-Hyung Lee[1], John P. Cullum[2], Sean A. Wiles[3], Tracy C. Leskey[4]

[1]USDA-ARS, U.S.A., [2]Virginia Polytechnic Institute and University, U.S.A., [3]Penn State University, U.S.A., [4]USDA-ARS, U.S.A.

It is well-established that adult Halyomorpha halys (Hemiptera: Pentatomidae) overwinter in human-made structures. However, little is known about overwintering ecology of this insect in the natural landscape. In a study spanning seven months from autumn to spring, we assessed 1,400 dead trees and 128 leaf litter samples to locate overwintering H. halys. Samples were taken in the two locations: small woodlots bordering agricultural production areas and large wooded tracts in mountainous areas. For dead trees, crevices under the tree bark were examined up to 3m above the ground. For leaf litter, samples were taken from 1 × 1m areas of the forest floor. In the dead trees, overwintering adult H. halys were found in nearly 4.0% of all trees examined. The mean number of adults per tree was 4.88 (± 2.25). Common traits of dead trees harboring overwintering H. halys adults included: 1) trunks with an upright or standing orientation, 2) oak or locust tree species, and 3) trees with a circumference > 60cm at chest height. Our results indicate that 11% of dead trees in the surveyed woodlots share all three characteristics and therefore could serve as overwintering harborages for H. halys. In the leaf litter, H. halys was never found, whereas native stink bugs including Chinavia hilare, Euschistus servus, and Menecles insertus were present in 16% of samples. The implication of H. halys populations overwintering in the natural landscape is discussed in the context of improving management programs for this invasive species.

The mechanism of the fecundity reduction in *Callosobruchus maculatus* caused by *Callosobruchus chinensis* males

Daisuke Kyogoku[1], Takayoshi Nishida[2]

[1]*Kyoto University, Japan,* [2]*The University of Shiga Prefecture, Japan*

Recent studies have reported that reproductive interference, or any kind of interspecific sexual interaction which reduces fitness of individuals involved, plays a crucial role in nature causing exclusive relationships between closely related species. However, our understanding of the mechanisms generating reproductive interference is still insufficient. Two congeneric bean weevils, Callosobruchus chinensis and C. maculatus, show asymmetric reproductive interference. Callosobruchus chinensis males reduce the fecundity of C. maculatus, but not vise versa. Here we investigated the mechanism of reproductive interference by C. chinensis males on C. maculatus females in terms of lifetime fecundity. Callosobruchus chinensis males with ablated genitals, which could harass C. maculatus females but not copulate with them, did not reduce the C. maculatus fecundity, suggesting that interspecific copulation was necessary. However, a single interspecific copulation did not affect C. maculatus fecundity as long as the females also copulated with a conspecific male. Exposure to C. chinensis males for 24 h prior to oviposition significantly reduced C. maculatus fecundity, and fecundity was negatively correlated with the number of C. chinensis males the females were exposed to. Moreover, C. maculatus females experienced more interspecific copulations when they were housed with more C. chinensis males. These findings suggest that multiple interspecific copulations by C. chinensis males reduce the fecundity of C. maculatus females. In general, even if a single interspecific copulation is apparently harmless, repeated interspecific copulations can be costly for the individuals involved. Furthermore, only by quantifying reproductive success were we able to identify the precise mechanism of reproductive interference.

Size-induced reproductive constraints in an egg parasitoid

Guy Boivin
Agriculture and Agrifood Canada, Canada

The size of adult parasitoids is influenced by the quantity and quality of resources available during immature development. Gregarious development of endoparasitoids results in scramble competition where the resources are shared among individuals developing within the same host. Individuals that developed gregariously are therefore smaller and that reduced size generally translates into lower fitness due to reductions in several life history traits including fecundity, longevity and mobility. This phenotypic plasticity in size also affects reproductive traits in parasitoids. We measured the reproductive constraints induced by size in Anaphes listronoti (Hymenoptera: Mymaridae), a facultative gregarious egg parasitoid of Curculionidae. Size decreased with number of immatures developing in a host egg for both male and female A. listronoti. This reduction in size resulted in fewer sperm being produced by males and fewer oocytes by females. Contrarily to other egg parasitoids, A. listronoti males are not prospermatogenic and produced some sperm during their adult life. Females that developed singly received a full sperm complement only when mated by a large male that also developed singly. When mating with a small male, a large female received less than half her sperm complement. Large males ejaculated about 50 sperm per mating and were able to mate four females before the number of sperm transfered started to decrease. When estimating fitness cost of gregarious development, it is important to take into account the reduced fertility of both males and females.

Influence of "*Candidatus Liberibacter asiaticus*" on the biological characteristics of *Diaphorina citri* Kuwayama

Yijing Cen[1], Fengnian Wu[2], Guangwen Liang[3]

[1]South China Agricultural University, China, [2]South China Agricultural University, China, [3]South China Agricultural University, China

Huanglongbing (HLB) is the most serious citrus disease. "Candidatus Liberibacter asiaticus" (Las) is one of the 3 Liberibacter species associated with HLB. Diaphorina citri Kuwayama (Hemiptera: Psyllidae) is the only known vector of Las. In this study, the biological characteristics of D. citri feeding on HLB-infected and healthy citrus were compared. The result showed that hosts affected by HLB had different influence on various life stages of the psyllids. The duration of eggs and 1-3 instars, survival rate of 1-2 instars, and sex ratio were not significantly different. Yet, for the former, the duration of 4-5 instars, total nymphs, pre-oviposition of females and the whole generation were significantly shortened; the fecundity and the period of adult laying eggs were significantly increased, and the survival rate of 3rd -5th instar nymths and generation were also significantly increased. The sex ratio of their offspring had no significant difference when feeding on both hosts. Although the egg hatching rate was significantly decreased, the Indice of Population Trend of the psyllids feeding on HLB-infected citrus was significantly higher than that on healthy citrus. These data indicated that infection of Las benefited the development of psyllid population. But, the tolerance to starvation of psyllids feeding on HLB affected hosts was significantly lower than those of feeding on healthy hosts. The mortality rate of overwintering adults feeding on HLB hosts was also significantly higher than those feeding on healthy plants. The detection rate of Las in the psyllids feeding on HLB hosts was 75%.

Thermal biology and population abundance of Mediterranean and Natal fruit flies, *Ceratitis capitata* and *Ceratitis rosa* (Diptera: Tephritidae) in South Africa

Casper Nyamukondiwa[1], Chris W. Weldon[2], John S. Terblanche[3]

[1]*Stellenbosch University, South Africa,* [2]*Pretoria University, South Africa,* [3]*Stellenbosch University, South Africa*

Understanding the link between field thermal biology and insect population dynamics under changing thermal conditions is of fundamental and applied importance and has significant implications for forecasting efforts. Here, we investigate several aspects of thermal biology and population dynamics in two pest fruit fly species, Ceratitis capitata and C. rosa, in South Africa both under laboratory and field conditions. Data on thermal limits across several life-stages, coupled with high resolution climate recordings, showed that upper and lower critical or lethal temperatures are seldom encountered in the field. Trap monitoring found that flies are active all year round, but abundance declines markedly during winter. Microclimate temperatures showed that the frequency and duration of suboptimal low temperatures e.g. lower developmental threshold is high and likely to suppress adult activity, mating, oviposition and development of immature stages. An integrated model that included a range of thermal responses under conditions that compromise development and survival was developed and used to predict changes in population abundance accurately. This model is of broad applicability to fruit fly management globally. These results suggest post-harvest orchard sanitation and adoption of an area-wide approach to fruit fly management may be critical for long-term reductions of Ceratitis populations in the region. This work provides an empirical framework for understanding the relationship between field thermal biology and population ecology of Ceratitis in agro-ecosystems, which is critical for the effective management of these flies.

Comparative population growth of the Psocid *Liposcelis yunnaniensis* (Psocoptera: Liposcelididae) on different humidities

Muhammad Waqar Hassan[1], Wei Dou[2], Jin-Jun Wang[3]

[1]The Islamia University of Bahawalpur, Pakistan, [2]Southwest University, China, [3]Southwest University, China

We investigated the effect of four different humidities on population growth of the psocid Liposcelis yunnaniensis (Psocoptera: Liposcelididae). The four different humidities used were; 43, 55, 63, and 75% respectively. In a 30 d period the initial four females psocids increased to the mean populations of 24 ± 5.72 on 75% humidity and 21 ± 3.45 on 63 % humidity. The psocids developing on 43 and 55 % showed no increase in their population and all the adult females psocids died in them. The results show that population growth was highest on higher humidities and the lower humidities of 43 and 55 % lead to the death of the insects. According to the analysis of variance there was no significant difference in the population growth between the higher humidities of 75% and 63% R.H. An analysis was also done with respect to the psocids placement in 4 different compartments of the incubator from top to bottom. It was found that there was no statistical difference in population growth of the psocids in different chambers of the desiccators which could be due to any variation in temperature inside the incubator. Psocid population growth is explained graphically with respect to different humidities and its placement on different heights of incubator.

The life history of Musca domestica reared on three diets (standard laboratory diet, SLD; solid waste diet, SWD; poultry manure diet, PMD) with additional 10% sucrose solution for the adults was studied based on the age-stage, two-sex life table considering both sexes and variable development rates among individuals. The study was conducted at laboratory conditions of 25 ± 2.2 ºC, 60 ± 5% RH and 12:12 h (L:D). Flies on SWD had shorter pupal duration (4.97 ± 0.07 days), shorter total preoviposition period (14.76 ± 0.18 days) and higher fecundity (401.31 ± 3.32 eggs per female) indicating that flies fed this diet were biologically more robust than those on SLD and PMD ($p < 0.05$). Longevity of females on SWD was the lowest possibly due to negative correlation between longevity and fecundity ($p < 0.01$). Overall, the population parameters indicate that M. domestica are r-strategists. Higher intrinsic rate of increase (0.2680 ± 0.0071 days-1), finite rate of increase (1.3073 ± 0.0093 days-1) and net reproductive rate (168.6 ± 20.0 offspring per individual) and shorter mean generation time (19.2 ± 0.2 days) of flies on SWD compared to SLD and PMD ($p < 0.05$) shows the greater nutritional suitability of SWD and potential for population growth. Age-stage specific survival (sxj), life expectancy (exj) and reproductive value (vxj) curves show life stage overlapping due to variation in development rates among individuals.

A comparison of red palm mite populations on banana in the invasive and naturalised range.

Bryony Taylor[1], Sean T. Murphy[2]

[1]CABI Europe-UK, United Kingdom, [2]CABI Europe-UK, United Kingdom

The Red Palm Mite (RPM) Raoiella indica (Acari:Tenuipalpidae) was first reported in the Caribbean in 2004 and has rapidly spread throughout the region and also into South America and Southern Florida. The mite was first reported in the Old World, in India (Hirst 1924) on coconut and its reported host range there prior to the invasion was relatively small, including: Coconut (Cocos nucifera), Date palm (Phoenix dactylifera) and Betelnut (Areca catechu). In the New World, high populations have been reported on many alternative hosts including the economically important banana, which remained unreported as an Old World host in the literature prior to 2010. To investigate why differences in RPM host range are being reported between the invasive and naturalised range, a series of studies were undertaken on banana. Survival analyses were conducted on local banana cultivars in India to establish whether banana is a potential host there. These indicated that RPM was able to survive and lay eggs on banana leaf sections thus having the potential for population establishment in the field, although performance differed between cultivars. A field survey was also undertaken in Kerala, India and Trinidad to estimate RPM and predator densities on banana, which indicated that predator densities and diversity were much higher in India on banana suggesting natural control of populations by predators on banana in this region. A simple population model developed from survival analysis results supported these findings.

Comparative life history and life tables between the two clones of *Sitobion avenae* (Fabricious) (Hemiptera: Aphididae) on barley yellow dwarf wirus infected barley

Zuqing HU[1], Huiyan Zhao[2], Thomas Thieme[3]

[1]Northwest A & F University, China, [2]Northwest A & F University, China, [3]BTL Bio-Test Labor GmbH, Germany

Life history and life tables of the brown and green clones of the apterous grain aphid, Sitobion avenae (Fabricius), were examined on barley yellow dwarf virus (BYDV) strain PAV infected, virus-free aphid pre-infested and on non-infected barley plants under the laboratory conditions of 20±1ºC, 65±5% RH and a photoperiod of 16:8 (L: D) h. Generally, both of the two S. avenae clones performed significantly better when fed on BYDV-infected plants compared with those fed on non-infected or virus-free aphid pre-infested plants. Furthermore, when fed on BYDV-infected plants, the green S. avenae clone developed significantly faster and had a significantly longer reproductive period compared with those of the brown clone. No significant differences were found for either clone of S. avenae when fed on non-infected or virus-free aphid pre-infested plants. The results showed that BYDV positively affected the performance of the two S. avenae clones, and particularly the green clone.

The glassywinged sharpshooter, *Homalodisca vitripennis* and the plant pathogenic bacterium, *Xylella fastidiosa* it vectors: Preparing Australia for invasion

Anna Rathe[1], Geoff M. Gurr[2], Leigh J. Pilkington[3]

[1]*Charles Sturt University, Australia,* [2]*Charles Sturt University, Australia,* [3]*NSW Department of Primary Industries, Australia*

The glassy-winged sharpshooter, Homalodisca vitripennis Germar (Hemiptera: Cicadellidae), is an important insect vector of the xylem-limited plant pathogen Xylella fastidiosa Wells which causes diseases in numerous plant species including food and feed stock crops, ornamentals and weeds. Both the pathogen and the vector are native to the Americas and are considered to be highly invasive but, to date, neither have been detected in Australia. Past invasions of the bacterium and vector have demonstrated the need for rapid detection and containment of an incursion. This requires a detailed knowledge of potential H. vitripennis and X. fastidiosa interactions and host plants in the invaded range. These host plant species can then be targeted for monitoring in order to detect an incursion at an early stage. Australian native plants naturalised in California provided an ideal opportunity to explore how the pathogen and vector, both also present in California, would interact with these plants if they were to arrive in Australia. Twelve Australian native plant species of interest were assessed as hosts of the pathogen and vector using field, greenhouse and laboratory studies in California, USA. Additional studies were undertaken to determine the risk of air transport as an invasion pathway, and the activity of the native enemy of H. vitripennis, parasitoid wasps, on Australian native plants. The results of the host status, invasion pathway and natural enemy research are presented and the implications of these findings discussed and placed in an Australian invasion context.

Difference in larval development and female oviposition preference in host plants between two populations utilizing different plants as larval hosts in an endangered lycaenid butterfly, *Zizina emelina*

Yoshiko Sakamoto[1], Norio Hirai[2], Minoru Ishii[3]

[1]Osaka Prefecture University, Japan, [2]Osaka Prefecture University, Japan, [3]Osaka Prefecture University, Japan

The bird's-foot trefoil, Lotus japonicus (Lj) (Fabaceae), has been known as a primary host plant of an endangered lycaenid butterfly, Zizina emelina. In the Kinki district, central Japan, a population in Kato City (KT), Hyogo Prefecture, utilizes Lj as a larval host, but a population depending on the white clover, Trifolium repens (Tr) (Fabaceae), was recently found in Toyonaka City (TN), Osaka Prefecture. In this study, we compared development of larvae fed with each of the two plants and oviposition preference of the resulting females in host plants in progenies of all combinations between KT and TN (all progenies). As for the larval development, the pupal weights of TN were about 51 and 48 mg in median in groups fed with Lj and Tr, respectively, and larger than those of KT (47 and 39). In all progenies the pupal weights of Lj fed groups were larger than those of Tr fed groups. Larval survival rates were not significantly different in all progenies fed with different host plants. Adult females of Lj and Tr fed groups in TN laid 30.9 and 42.1% eggs on Tr, respectively, while those in KT oviposited very few eggs (0.8 and 0.0%) on Tr. The pupal weight and oviposition preference of the hybrids were intermediate between those of TN and KT. The number of eggs laid per female was correlated with the pupal weight. The results show that females of TN lay more eggs and larval development is better on Tr than those of KT.

Effect of host plant on life history and population growth parameters of the invasive mango mealybug, *Rastrococcus iceryoides* Green (Hemiptera: Pseudococcidae) in Africa

Tanga Mbi Chrysantus[1], Sunday Ekesi[2], Samira Mohamed[3], Govender Prem[4]

[1]University of Pretoria, Cameroon, [2]International Centre of Insect Physiology and Ecology, Kenya, [3]International Centre of Insect Physiology and Ecology, Kenya, [4]University of Pretoria, South Africa

The effect of four cultivated host plants namely Mangifera indica L., Cajanus cajan (L.) Millspaugh, Coffee arabica L. and Cucurbita moschata Duchesne, and two important ornamental plants namely Parkinsonia aculeata L. and Ficus benjamina Roxb., on the biology of the mango mealybug, Rastrococcus iceryoides Green (Hemiptera: Pseudococcidae) was studied in screen houses at 22.3 ± 5.07˚C, 70 ± 5% relative humidity and 12L:12D photoperiod. The development, survivorship, longevity, reproduction and life table parameters of R. iceryoides differed significantly among the plant species. The shortest developmental period (from egg to adult) was recorded on M. indica (23.5 ± 0.34 days for females) whereas the longest was recorded on F. benjamina (33.0 ± 0.62 days). The highest egg to adult female R. iceryoides survivorship was recorded on C. moschata (79.6 ± 1.4%) and the lowest was on C. arabica (30.9 ± 1.1%). The highest fecundity was observed on C. moschata (811.3 ± 7.3 eggs). The sex ratio was female-biased on C. moschata, M. indica, C. cajan and P. aculeata. Body size was influenced by the different host plant types. Maximum values of the intrinsic rate of natural increase (rm), finite rate of increase (λ) and the shortest mean generation time (GT) and doubling time (Td) were recorded on M. indica. This implies that M. indica is the most preferred compared to the other host plants. Results of this study are useful in understanding the roles of host plants in integrated management of this pest, including exploitation of these plants in push-pull control.

Modeling temperature-dependent development of pistachio psylla, *Agonoscena pistaciae* (Hemiptera: Psyllidae)

Mohammad Reza Hassani[1], Abbas Arbab[2]

[1]*Rafsanjan Branch, Islamic Azad University, Iran,* [2]*Takestan Branch, Islamic Azad University, Iran*

The pistachio psylla, Agonoscena pistaciae Burckhardt & Lauterer (Hemiptera: Psyllidae) is a major pest of pistachio trees throughout pistachio producing regions in Iran. The objective of this work was to evaluate which linear and nonlinear model, (Stinner aplo, Janisch, Taylor, Sharpe & DeMichele, Lamb, Lactin and Briere) best describes the relationship between developmental rates of the egg, nymph and egg to adult of A. pistaciae, and temperature. The pistachio psylla eggs and nymphs were reared on pistachio leaves (Pistacia vera L., cultivar Ohadi) at constant temperatures of 15, 20, 25, 30, 32.5 and 35±0.5ºC. The models were evaluated based on four indicators; (R2, RSS, AIC and R2adj). For egg, the linear model and nonlinear models, Stinneraplo, Lamb, Taylor, Sharp & DeMichele and Lactin, appropriately described the relationship between the developmental rate and temperature. For nymph and egg to adult, the nonlinear models are not appropriate to describe the observed data accurately. Using the linear model the lower temperature threshold for egg, nymph and egg to adult was estimated 8.06, 10.38 and 9.97ºC, respectively. The similar value of lower temperature threshold was estimated by Lactin model especially for egg (8ºC). Thermal constant for egg, nymph and egg to adult development by linear model was estimated 88.5, 243.90 and 333.33 DD, respectively. Our results showed that, the linear model better describe the relationship between developmental rate and temperature of A. pistaciae. These results could be incorporated in forecasting models for integrated pest management of this pest.

Multiple mating and its effect on fitness of *Diaeretiella rapae* (Hymenoptera: Aphidiidae)

Rashmi Kant[1], Maria A. Minor[2], Steve Trewick[3]

[1]Massey University, New Zealand, [2]Massey University, New Zealand, [3]Massey University, New Zealand

Mating frequency and the amount of sperm transferred during mating have important consequences on progeny sex ratio and fitness of haplodiploid insects. Production of female offspring depends primarily upon the availability of sperm for fertilising eggs. This study examined multiple mating and its effect on fitness of the cabbage aphid parasitoid Diaeretiella rapae (Hymenoptera: Aphidiidae). Female D. rapae mated once, while males mated with on average more than 3 females in a single day. The minimum time lag between two consecutive matings by a male was 3 min, and the maximum number of matings a male achieved in a day was 8. Sperm depletion occurred as a consequence of multiple mating in D. rapae. The number of daughters produced by females that mated with multiple-mated males was negatively correlated with the number of matings achieved by these males. Similarly, the proportion of female progeny decreased in females that mated with males that had already mated 3 times. Although the proportion of female progeny resulting from multiple mating decreased, the decrease was quicker when the mating occurred the same day than when the matings occurred once per day over several days. Mating success of males initially increased after the first mating then decreased with the number of prior matings. The fertility and the progeny sex ratio of females were affected by mating with multiple mated males. Study suggests that male mating history affects the fitness of male and female D. rapae.

Invasive insect pests of forests in the Southern Appalachians, USA: Assessment and management of multiple pests to enhance forest health

Jerome F. Grant[1], Paris L. Lambdin[2], Gregory J. Wiggins[3], James Rusty Rhea[4]

[1]University of Tennessee, USA, U.S.A., [2]University of Tennessee, USA, U.S.A., [3]University of Tennessee, USA, U.S.A., [4]United States Forest Service, U.S.A.

Multiple introduced and invasive exotic insects, weeds, and plant diseases currently impact forest health in the southeastern United States, where forests are comprised of numerous tree species. Three of these species, ash (Fraxinus spp.), black walnut (Juglans nigra), and eastern hemlock (Tsuga canadensis), are currently threatened by invasive insect pests. The hemlock woolly adelgid, Adelges tsugae, has been present on hemlocks in southern forests since 2002 and has killed tens of thousands of eastern hemlock trees. In 2010, the emerald ash borer and thousand cankers disease (TCD) (caused by a fungal pathogen, Geosmithia morbida, vectored by the walnut twig beetle, Pityophthorus juglandis) were found on ash and black walnut trees, respectively, in the southern United States. Although TCD has not yet been recovered from a forest setting, its documentation in urban habitats was the first comfirmation of TCD in the native range of black walnut and the first incidence of either pest problem in the southern United States. The presence of emerald ash borer in Tennessee represents the most southern distribution of this invasive pest in the U.S. The presence of emerald ash borer and TCD in Tennessee provides a tremendous opportunity to expand research and outreach activities to better understand these invasive organisms in the southern United States. Knowledge gained here can be applied throughout the native range of black walnut to enable scientists to develop better management strategies to limit the impact of this devastating disease and to enhance management efforts against emerald ash borer in southern areas.

Biological base of IPM against phytophages on strawberry plantations

Sergey Yakovlevich Popov
Russian Timiryazev State Agrarian University, Russia

IPM against a number of insects (mainly strawberry blossom weevil Anthonomus rubi Herbst, strawberry leaf-roller Ancylis comptana Frol.) and mites (mainly Tetranychus atlanticus McGregor) on strawberry plantations in the Central Russia has been constructed on the base of long-term observations. Life tables, phenology, plant injury calculation methods were used. Phytophages monitoring was carried out on each plot of 2-2.5 hectares. Main insect control criteria included thresholds of harmfulness (for A. rubi ? 0.1-0.25 beetle, for A. comptana ? 8-12 caterpillars per 1 linear m of row at the period of first visible flower buds), for spider mite control ? prevention the population density of 35-40 individuals (excluding eggs) per 1 leaflet at fruit formation period. The threshold of harmfulness of A. rubi on tolerant strawberry varieties could be increased to 0.66 beetles per 1 linear m. Outbreaks of spider mite populations were expected when the density of overwintered females was 0.4 and more per 1 leaf and when the mean decade temperature at each of 4-5 following decades reached or could be above 13.5-14°C. In these years, the net reproduction rate (R0) of the overwintered population was 46-65, and that of the first summer generation reached 80-95. When the economic level of spider mite damage was expected at the period of fruit formation, one of the predatory mite species of Neoseiulus was used at the period of blooming. In some years, we could exclude chemical treatments on the half of the 200 hectares of strawberry plantations.

Synthetic substrate-borne vibrational signals that elicit Asian citrus Psyllid communicatory and search responses

Richard Wendell Mankin[1], Elizabeth Heatherington[2]

[1]USDA-ARS, U.S.A., [2]USDA-ARS, U.S.A.

The Asian Citrus Psyllid (ACP), Diaphorina citri Kuwayama, vectors a harmful bacterium, Candidatus Liberibacter asiaticus, that causes huanglongbing, an economically devastating disease of citrus. Adult male and female ACP transmit vibratory communication signals over 10-50-cm distances within their citrus tree hosts by producing wing-fanning vibrations. Males begin calling while searching for females. When a receptive female detects these signals, she replies in a duet that facilitates location of her position. This report describes explorations of new methods that use such signals to efficiently detect and trap ACP males for facilitation of targeting and control efforts. In preliminary studies, mating communication signals of virgin adult male/female pairs were recorded on citrus seedlings at 3-7 days post eclosion. Candidate signals were played back to elicit responses from other psyllids on new seedlings. A series of synthetic calls was constructed, based on the mean durations and spectral harmonics of male and female signals. The synthetic calls were tested using a vibration exciter attached to the host tree. The elicited behaviors were monitored and recorded. The results were compared to each other, as well as to results from playbacks of recordings from males and females. In general, the more harmonics that were present in the synthetic song, the greater the likelihood that a female would reply or that the male would orient to the signal. A goal of future studies is to devise an inexpensive, efficient trap for males, and ultimately to broadcast synthetic signals that can be used to interfere with mating.

Assessment of the effect of inflorescence density index of grain amaranth (*Amaranthus* Spp.) on *cletus fuscescens* infestation.

Abiola Olufunke Oke[1], Thomas I. Ofuya[2]

[1]*National Horticultural Research Institute, Nihort, Nigeria,* [2]*Federal University of Technology, Akure, Nigeria*

ABSTRACT. The effect of inflorescence density index of grain amaranth on Cletus fuscescens attack was studied during the early seasons of 2009 and 2010 in the experimental field of National Horticultural Research Institute, Ibadan. Accessions tested were 'RRC 646', 'P 373' and Oscar Blanco, (all with lax inflorescence density index), 'RRC 1027', 'Tibet' and Niqua, (all with intermediate inflorescence density index) and 'D70-1', 'RRC 551' and Zhen Ping, (all with dense inflorescence density index). All the 3 accessions with intermediate inflorescence density index had highest Cletus fuscescens populations/ plant and least viability percentage while all the 3 accessions with dense inflorescence density index had lowest C. fuscescens populations/ plant and highest viability percentage. C. fuscescens populations/ plant established a strong negative relationship with only viability percentage. Also stepwise regression analysis selected viability percentage as the most powerful variable reflecting C. fuscescens infestation. This result suggests that dense inflorescence density index in grain amaranth contributed to reduction in bug infestation which indicates high seed viability percentage and grain quality.

Management strategies for the invasive fruit fly, *Bactrocera invadens* in Africa

Sunday Ekesi [1], Samira A. Mohamed[2], Fathiya M. Khamis[3], Nguya K. Maniania[4]

[1]ICIPE, Kenya, [2]ICIPE, Kenya, [3]ICIPE, Kenya, [4]ICIPE, Kenya

Bactrocera invadens (Diptera: Tephritidae) is a recently described fruit fly species of major quarantine concern. It attacks a variety of fruits and vegetables but mango is the preferred host plant. We evaluated various synthetic food-based attractants that could be used in combination with entomopathogenic fungi (EPF) against adults and for soil inoculation targeting pupariating larvae and puparia. The field performance of Mazoferm and GF-120 spinosad bait spray in combination with Metarhizium anisopliae-based biopesticide will be presented. Since native fruit fly parasitoids do not play an important role in the management of B. invadens, exploration for natural enemies of the pest in its putative aboriginal home of Sri Lanka was undertaken. Exploration yielded a diversity of parasitoids and predators but none has been introduced into Africa for management of B. invadens due to restrictions related to Convention on Biological Diversity. However, two exotic parasitoids (Fopius arisanus and Diachasmimorpha longicaudata) have been introduced from Hawaii for the control of B. invadens in Africa. The potential of these parasitoids in the management of the pest is examined and results from ongoing field release efforts that are complementing other management methods based on baiting and male annihilation technique, use of biopesticides and orchard sanitation for the management of the invasive fruit fly in Africa are presented. In addition to pre-harvest management measures, results will be presented on post-harvest treatment parameters that have been developed to facilitate access to quarantine sensitive markets.

Improved attraction of the strawberry blossom weevil *Anthonomus rubi* by combining the aggregation pheromone with specific host flower volatile

Atle Wibe[1], Anna-Karin Borg-Karlson[2], Jerry Cross[3], Lene Sigsgaard[4], Ilme Liblikas[5], Helena Bichao[6]

[1]Bioforsk - Norwegian Institute for Agricultural and Environmental Research, Norway, [2]KTH - Royal Institute of Technology, Sweden, [3]EMR - East Malling Research, United Kingdom, [4]University of Copenhagen, Denmark, [5]Tartu University, Estonia, [6]Nofima - The Norwegian Institute of Food, Fisheries and Aquaculture Research, Norway

In the absence of effective control measures, the strawberry blossom weevil (Anthonomus rubi) cause large losses in both conventional and organic grown strawberry in northern and central Europa. The present study aimed to investigate the significance of plant volatiles in combination with the aggregation pheromones to develop an effective semiochemical trap for the management of A. rubi. The aggregation pheromone has been available for several years. However, it has shown low attractancy. In the present study host plant volatiles from wild strawberry (Fragaria vesca) and cultivated strawberry (F. ananassa) were collected by SPME. These volatiles were chemical identified using GC-MS. The volatile blends of F. vesca and F. ananassa were dominated by one and six different compounds respectively. For both plant species other compounds were also identified. To test the significance of the major flower volatile of F. vesca and one other relevant compound from F. ananassa in combination with the aggregation pheromone field experiments were established in Norway, Denmark and UK. Green funnel traps with white cross veins were used for the evaluations. The results shows that the traps baited with plant volatiles didn't attract more A. rubi than control traps without baits. However, traps baited with the major flower volatile from wild strawberry flowers and the aggregation pheromone increased trap catches by over two fold compared to the pheromone alone. Thus, the combined use of the aggregation pheromone and this flower volatile is promising for improved monitoring and possibly control of this important pest of strawberry.

Stylet penetration activities of tomato/potato Psyllid associated with acquisition and inoculation of *Candidatus Liberibacter solanacearum*

Manoharie Sandanayaka[1], Aranzazu Moreno[2], Leah Tooman[3], Natalie Page-Weir[4], Alberto Fereres[5]

[1]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [2]Spanish Council for Scientific Research, CSIC, Instituto de Ciencias Agrarias, ICA, Spain, [3]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [4]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [5]Spanish Council for Scientific Research, CSIC, Instituto de Ciencias Agrarias, ICA., Spain

The stylet penetration activities relating to acquisition and inoculation of Candidatus Liberibacter Solanacearum (CLso) by a single Tomato/Potato Psyllid (TPP), Bactericera cockerelli, on tomato were studied using electrical penetration graph (EPG-DC system) recordings. Female TPP from CLso-positive and negative colonies were used in inoculation and acquisition tests, respectively. The presence or absence of CLso in positive and negative colonies, donor plants used in acquisition tests, plant material after inoculation tests and insects after EPG tests, was confirmed by PCR tests. In the acquisition tests, the stylet penetration activities of 70 TPP were monitored on excised shoots of CLso-positive tomato plants for 4-24 hours. In the inoculation tests, the stylet penetration activities of 60 individual TPP were monitored on 60 healthy (CLso free) tomato plants for 12-24 hours. Durations of EPG waveforms (C, G, D, E1 and E2) representing the main stylet penetration activities of individual insects in different acquisition and inoculation access periods were measured. Results confirmed that a single adult TPP can inoculate CLso and cause damage to a plant. The relationship between EPG waveforms and PCR results suggest that acquisition occurred during phloem ingestion (E2) and inoculation was preferentially associated with salivation into the phloem sieve elements (E1). The minimum plant access period required for CLso transmission by a single TPP was estimated, to assist growers in making effective management decisions to reduce the impact of this serious disease.

Oviposition preferences of codling moth, *Cydia pomonella* (L.) (Lepidoptera: Tortricidae) and an oviposition preference-based susceptibility index for apple cultivars

Neelendra K. Joshi[1], Larry A. Hull[2], Edwin G. Rajotte[3], Clayton T. Myers[4], Greg Krawczyk[5]

[1]Penn State University, U.S.A., [2]Penn State University Fruit Research & Extension Center, U.S.A., [3]Penn State University, U.S.A., [4]U.S. Environmental Protection Agency, U.S.A., [5]Penn State University Fruit Research & Extension Center, U.S.A.

Oviposition preferences of the codling moth (CM), Cydia pomonella (L.) (Lepidoptera: Tortricidae) for the fruits of different apple cultivars were studied in laboratory bioassays using a series of no-choice and multiple-choice tests. During the first two years of study, ten apple cultivars viz., Arlet, Fuji, Gala, Golden Delicious, Honeycrisp, Pristine, Delicious, Stayman, Sunrise, and York Imperial were evaluated, while in the third year, Golden Delicious, Honeycrisp and York Imperial were evaluated. In the first year's tests, preferred apple cultivars for CM oviposition were Golden Delicious and Fuji, while the least preferred were Arlet, Pristine, Sunrise, and Honeycrisp. Similarly, during the second year, Golden Delicious, Fuji and Stayman remained the preferred cultivars, while Arlet, Honeycrisp, Pristine, and Sunrise remained the least preferred cultivars. In the third year's tests, Golden Delicious and Honeycrisp were the most and least preferred cultivars, respectively. Based on the oviposition preferences from these bioassays, a CM oviposition susceptibility index for each cultivar was developed. This index may be used as a standard measure in cultivar evaluations and may assist fruit growers and consultants to select the most appropriate cultivar(s) for monitoring and detecting the initial signs of fruit injury from this pest in an apple orchard planted with mix-cultivars. Oviposition in CM is likely stimulated by fruit volatiles, and variations in the production and release of these volatiles from different apple cultivars may result in different oviposition preferences. Further investigations are needed to understand biochemical aspects and other factors involved in determining the oviposition preference of CM.

Effects of electron beam on life stages and DNA damage of American serpentine leafminer, *Liriomyza trifolii* (Burgess)

Seung Hwan Yun[1], Hyun-Na Koo[2], Gil Hah Kim[3]

[1]*Chungbuk National University Republic of Korea, Republic of Korea,* [2]*Chungbuk National University, Republic of Korea,* [3]*Chungbuk National University, Republic of Korea*

The American serpentine leafminer fly, Liriomyza trifolii (Burgess), is one of the most destructive polyphagous pests worldwide. In this study, we determined electron beam doses for inhibition of normal development of the leaf miner and investigated the effect of electron beam irradiation on DNA damage and p53 stability. Eggs (0 - 24 h old), larvae (2nd instar), puparia (0 - 24 h old after pupariation) and adults (24 h after emergence) were irradiated with increasing doses of electron beam irradiation (six levels between 30 and 200 Gy). At 150 Gy, the number of adults that developed from irradiated eggs, larvae and puparia was lower than in the untreated control. Fecundity and egg hatchability decreased depending on the doses applied. Reciprocal crosses between irradiated and unirradiated flies demonstrated that males were more radiotolerant than females. Adult longevity was not affected in all stages. The levels of DNA damage in L. trifolii adults were evaluated using the alkaline comet assay. Our results indicate that electron beam irradiation increased levels of DNA damage in a dose-dependent manner. Moreover, low doses of electron beam irradiation led to the rapid appearance of p53 protein within 6 h; however, it decreased after exposure to high doses (150 Gy and 200 Gy). These results suggest that electron beam irradiation induced not only abnormal development and reproduction but also p53 stability caused by DNA damage in L. trifolii. We conclude that a minimum dose of 150 Gy should be sufficient for female sterilization of L. trifolii.

Lac insects cultivation, ecological and economical importance of lac agroecosystems in China.

Youqing Chen[1], Xiaoming Chen[2]

[1]Research institute of resource insects, Chinese academy of forestry, China, [2]Research institute of resource insects, Chinese academy of forestry, China

Lac is a layer of red resin on branches of host-trees on which lac insects settle. Lac resin is natural, biodegradable and non-toxic, and thus widely used in food, textiles and pharmaceutical industries in addition to surface coating, electrical component manufacturing, and other fields. Several lac insect species and many species of plant trees were collected around the world in China. Some lac insect species have been used to produce lac after many years' domestication. To increase lac yield, the ecological and biological features of lac insects including the relationship between lac insects and host plants, the ways of controlling pests of lac insects and so on were focused on by many researches. The current prosperity in the lac market provides an incentive for farmers to increase lac production. Lac-production and farming were integrated into an agroforest system. Farmers there enjoyed both cash income and non-cash benefits from these multipurpose lac plants, especially the increased soil fertility and soil retention, with limited labor input, in that fragile environment. Under a diverse and thin canopy of lac plants with lac insects, the compounded system harbored a high biodiversity of associated organisms. During the past fifty years, this traditional farming system has been modified by agricultural conversion. Lac systems have either intensified into other food crop agricultural systems following habitat clearing, or abandoned resulting in natural afforestation. Here we illustrate the ecological and economical importance of these agroecosystems, and hope to attract more attention to this valuable agroecosystem.

Going underground - enhanced detection approaches for root feeding grape phylloxera

Kevin Steven Powell[1], Rebecca J. Bruce[2], Devin Benheim[3], Simone J. Rochfort[4]

[1]DPI-Victoria, Australia, [2]DPI-Victoria, Australia, [3]DPI-Victoria, Australia, [4]DPI-Victoria, Australia

Grape phylloxera (Daktulosphaira vitifoliae Fitch) is present in most grape-growing countries and can attack both the roots and foliage of grapevines, depending on the genetic lineage of the insect. The root-galling form of phylloxera causes significant economic damage to European grapevine (Vitis vinifera L.) and can also survive on the roots of 'resistant' Vitis rootstocks. Phylloxera detection primarily still relies on visual examination of the grapevine root system and relies on detecting 'weak' spots in the grapevine canopy caused by extensive root damage which often takes years to become evident. Early detection of root feeding phylloxera needs to consider a more targeted approach where the influence of soil physiochemical properties on phylloxera establishment and subsequent dispersal are recognised and where the host plant response, in the form of changes in host plant chemistry, can be used as a secondary indicator of root feeding. Novel options for targeted early detection of phylloxera are being developed, where soil factors are considered, include the use of a soil molecular DNA probe, trapping techniques and soil electromagnetic induction surveys. These techniques can also be combined with the use of spectrochemical sensing to enhance sensitivity. An overview of a novel early detection system under development in Australia will be presented.

Cockchafer distribution, species diversity and seasonal abundance in Gippsland, Victoria: Preliminary findings

Rebecca Jane Bruce[1], Kevin Steven Powell[2], Amy Cosby[3], Mark Trotter[4], John Stanley[5], Greg Falzon[6], Alan Louey Yen[7], David Lamb[8]

[1]Department of Primary Industries, Biosciences Research Division, Rutherglen, Victoria 3685., Australia, [2]DPI-Victoria, Australia, [3]Precision Agriculture Research Group, University of New England, Armidale NSW 2351, Australia, [4]Precision Agriculture Research Group, University of New England, Armidale NSW 2351, Australia, [5]Precision Agriculture Research Group, University of New England, Armidale NSW 2351, Australia, [6]C4-D (Spatio-temporal Analysis Research Group), University of New England, Armidale NSW 2351, Australia, [7]Department of Primary Industries, Biosciences Research Division, Knoxfield, Victoria, Australia, [8]Precision Agriculture Research Group, University of New England, Armidale NSW 2351, Australia

Red Headed Cockchafer (RHC) Adoryphorus couloni (Bermeister) is a native pest of ryegrass-based cattle pastures in South Eastern Australia. Detection is often only after extensive plant damage occurs, with the predominant management technique then being to remove and re-sow pasture. Anecdotal evidence suggests that soil characteristics, vegetation and moisture may influence RHC distribution and population density, though few studies have been conducted to qualify this influence. Other cockchafers such as African Black Beetle Heteronychus arator and Black Headed Cockchafer Acrossidius tasmaniae (Aphodius tasmaniae) may occur simultaneously, and the influence of soil characteristics on their distribution is also unknown. Understanding this influence on cockchafer distribution could lead to improved early detection and targeted management of these pests. In a preliminary 2011 study three regions in Gippsland, Victoria were surveyed using manual soil sampling and on-the-go proximal sensing techniques to (i) investigate any association between soil electrical conductivity (a widely-used surrogate indicator of soil texture, moisture content and/or salinity) and above-ground pasture biomass and the spatial distribution of cockchafer in dairy paddocks, (ii) to quantify the relative abundance of each species in the three regions and (iii) collect preliminary data to determine seasonal distribution of cockchafer life-stages in each region. Results indicated that not all species were found together in all regions, and that a potential link between soil characteristics and cockchafer distribution may exist. It also highlighted that detailed population dynamics studies are a fundamental prerequisite for optimising control on-farm. This research forms part of an ongoing 3 year study (2011-2014)

Grapevine phylloxera: An integrated approach to management of a phylloxera clonal lineages in Australia

Kevin Steven Powell[1], Ginger A. Korosi[2], Rebecca Jane Bruce[3]

[1]DPI-Victoria, Australia, [2]Department of Primary Industries, Biosciences Division, Rutherglen VIC 3685, Australia, [3]Department of Primary Industries, Biosciences Division, Rutherglen VIC 3685, Australia

Grapevine phylloxera Daktulosphaira vitifoliae Fitch attacks the roots and leaves of commercial and ornamental grapevines and has spread to most grape-growing countries. It was first detected in Australia in 1877 and is currently restricted to areas in Victoria and New South Wales primarily through quarantine and the use of resistant rootstocks. Phylloxera 'outbreaks' have been increasing in Australia in the last decade. To restrict spread of the insect an integrated approach to management is under development which considers critical stages of the insects' life cycle and three phases of management (i) detection and surveillance (ii) screening for resistant host plant material (iii) quarantine and disinfestation procedures and (iv) grower awareness. All three management approaches are influenced by the diversity and virulence of phylloxera clonal lineages. To develop resilient rootstock resistance ratings a triphasic approach, using laboratory, glasshouse and field protocols, was conducted using six phylloxera clonal lineages and ten rootstock types. The efficacy of chemical and physical disinfestation treatments for viticultural machinery and grape products and the importance of adherence to quarantine protocols is also highlighted. Dry heat treatment proved effective as a disinfestation treatment for first instar grape phylloxera at temperatures of >40 C. Several factors influenced survival of phylloxera in white grape juice including settling temperature and added sulphur. All outputs from research are delivered to growers at annual National Phylloxera Management workshops.

Study on occurrence characteristics of *Eucryptorrhynchus chinensis* (Olivier) (Coleptera:Curculioniclae) in Lingwu, Ningxia

Qianqian Yu[1], Chong Chen[2], Junbao Wen[3]

[1]Beijing Forest University,Beijing P.R.China, China, [2]Beijing Forest University,Beijing P.R.China, China, [3]Beijing Forest University,Beijing P.R.China, China

The survey on damage and occurrence characteristics of Eucryptorrhynchus chinensis (Olivier) in Lingwu, Ningxia, revealed that different sites have varied degrees of damage by this pest because of invasive sequence. The damage is most serious in Linhe Town, while less serious in Chongxing Town. E. Chinensis larvae damage the roots of Ailanthus altissima, then stimulate them to form nodules, and lead to fracture of the roots. The adults feed on the exposed roots, the parts with gum or the trunk base,or feed on and wither the shoots. During the recent two years, E. chinensis adults peaked at late June and late August, late May and early July, respectively. About 80% of E. chinensis larvae were found in a soil layer from the surface to as deep as 45 cm underground. The larvae emerge in large numbers in soil from early May to late June. Unearthed extent of most E. chinensis ranges from the base of the trunk to about 75 cm outwards, account for 88% of the total number. Based on damage characteristics of E. chinensis mentioned above, it is practical to catching and killing this pest during its peak. In addition, in chemical control, it may be effective to take into account different orientations and extend the depth and range of the application of pesticide. The optimal time to apply pesticide is May or June, when the larvae occur in large numbers in soil.

Resistance of onion cultivars to thrips (Thysanoptera: Thripidae) and Iris yellow spot virus in Kenya

Rael Kayume Birithia[1], Rama Narla[2], James Muthomi[3], Sevgan Subramanian[4]

[1]International centre of insect physiology and Ecology(ICIPE), Kenya, [2]University of Nairobi, P.O. Box 30197, Nairobi, Kenya, [3]University of Nairobi P.O. Box 30197, Nairobi, Kenya, [4]International Centre of Insect Physiology and Ecology (icipe), P.O. Box 30772-00100, Nairobi, Kenya

Iris yellow spot virus (IYSV) vectored by Thrips tabaci Lindeman, threaten onion (Allium cepa L.) production in Kenya. Insecticides are widely used for vector management resulting in pesticide resistance and increased virus spread. Information on resistance among commonly grown onion cultivars to IYSV and T. tabaci is crucial for the development of integrated virus management strategies, but often lacking. Therefore, this study focused on screening commonly grown onion cultivars (Red pinnoy, Red creole, Bombay red, Green bunching and Texas grano) for thrips and IYSV resistance, in two season field trials conducted at University of Nairobi, Kabete. Each onion variety was replicated four times and arranged in a randomized complete block design. Natural thrips and IYSV infestation occurred and Straw-colored, necrotic lesions typical of IYSV infection was observed two weeks after transplanting. Ten randomly selected plants per plot were rated for IYSV severity and thrips infestation levels. Disease incidence was scored by calculating (number of IYSV infected plants/ total number of plants per plot).The virus titre was determined by DAS-ELISA. Cultivars differed significantly for both disease incidence ($F_{4,44}=5.36$; $P<0.0001$) and thrips infestation levels ($F_{4,44}= 3.67$; $P<0.001$) from fourth week. Red pinnoy, Green bunching and Red creole were more susceptible to the virus and thrips as compared to Texas grano and Bombay red. There were significant differences among cultivars for increase in the virus titre level over time. However, optical densities correlated positively with disease severity ($R=0.663$; $P=0.05$). Texas grano and Bombay red exhibited some tolerance both to thrips and IYSV.

Dispersal and population genetic structure in codling moth at different spatial scales

Eduardo Fuentes Contreras[1], Esteban Basoalto[2], Alejandra Basoalto[3], Claudio Ramirez[4], Blas Lavandero[5], Pierre Franck[6]

[1]Universidad de Talca, Chile, [2]Universidad de Talca, Chile, [3]Universidad de Talca, Chile, [4]Universidad de Talca, Chile, [5]Universidad de Talca, Chile, [6]INRA, France

Codling moth, Cydia pomonella (Lepidoptera: Tortricidae) is the main pest of pome fruits worldwide. Area wide management strategies of this pest have been used in different countries with different levels of success. Dispersal and gene flow between populations in managed and unmanaged habitats seems to be an important factor to explain such variable results. We used microsatellite molecular markers to estimate codling moth dispersal and gene flow at different spatial scales from country (1800 km) region (250 km) and local scale (< 1 km) in apple producing areas from Chile. In addition, we used immunomarking techniques to estimate dispersal at local scale. We have found low genetic differentiation (Fst) and high gene flow between codling moth populations at different spatial scales, with only slight isolation by distance at larger spatial scales. Bayesian assignment tests also support the low levels of population genetic structure among locations and host-plants. Dispersal studies at local scale using immunomarking techniques support the relevance of adult dispersal to explain the low levels of population differentiation. Anthropic influence on agroecosystems is a main driver of dispersal and gene flow of this pest at different spatial scales.

Simulation of distributional pattern of leafhopper with GIS

Satoshi Kamitani[1], Shun Kumashiro[2]

[1]Kyushu University, Japan, [2]Kagoshima University, Japan

The evacanthine leafhopper genus, Pagaronia (Hemiptera, Cicadellidae), is distributed in the eastern Palaearctic region and the western Nearctic region, and highly diversified especially in Japan. This high diversification, about 100 species has been described from Japan, is one of interesting evolutionally processes to discuss leafhopper classification. The authors guessed that the allopatric distribution and narrow distribution area of each species should be related to the diversification processes, because these features are not found within the other leafhoppers. Three Pagaronia species distributed in northern Kyushu were used in this study: the distribution of them is completerly allopatric. As the geology, current flora and distribution of large rives in Kyushu were not consistent with the actual distribution pattern of them, two computer simulations with GIS were performed by a Visual Basic Program. A simulation based on the mean annual temperature was not also consistent with the actual distribution pattern. The predicted distributions of them were overlapped. However, a simulation based on the geographical feature, "watershed", was strongly consistent with it. In this simulation, we assumed that leafhoppers can't go over large rivers because they don't fly in middle or long distance. The watersheds between Matsuura River - Rokkaku River, Mikasa River - Chikugo River, and Midori River ? Gokase River are very important for the determination of their distribution.

Using thermal tolerance traits to test distribution model outcomes for an invasive mite, *Halotydeus destructor*

Matthew Hill[1], Ary Hoffmann[2]

[1]*University of Melbourne, Australia,* [2]*University of Melbourne, Australia*

Invasive species cause massive losses to biodiversity and agricultural production globally. Species distribution modelling is often used to predict distributions for invasive species, however, there is little empirical research to test hypotheses generated from these models. The redlegged earth mite, Halotydeus destructor, is native to South Africa and was first reported in Australia in 1917 where it has since established as a major agricultural pest. In the last 40 years this species has expanded into hotter and drier areas. Recently, species distribution models were applied to H. destructor in both its native and invasive ranges and suggested niche-shift to facilitate range expansion for this species. Halotydeus destructor presents a unique opportunity to test species distribution model hypotheses by investigating thermal tolerance traits across a known pathway of invasion and across areas of range expansion. We selected populations of H. destructor from environments in both South Africa and Australia predicted to occupy different niches. Upper activity limits and critical thermal minimum (CTMIN) were tested on field-collected populations of H. destructor. We also tested for effects of acclimation on CTMIN to determine levels of plasticity between native and invasive ranges. Halotydeus destructor populations in Australia have a marginally higher upper activity limit, and are able to recover from CTMIN more rapidly than the South African populations. Australian populations also have higher plasticity than native South African populations. Our results demonstrate that species distribution models provide important foundations to direct explicit testing of traits that may shift between geographic ranges following species invasions.

Linking vegetation indexes from remote sensing and long-term prospection data to help in the preventative control of desert locust

Cyril Piou[1], Valentine Lebourgeois[2], Ahmed Salem Benahi[3], Mohamed el Hacen Jaavar[4], Vincent Bonnal[5], Jean-Michel Vassal[6], Michel Lecoq[7]

[1]CIRAD, France, [2]CIRAD, France, [3]CNLA, Mauritania, [4]CNLA, Mauritania, [5]CIRAD, France, [6]CIRAD, France, [7]CIRAD, France

Desert Locust management is nowadays done through a preventative control strategy that consists in avoiding populations to reach high densities and a gregarization process leading to uncontrollable swarms. The areas of potential start of the gregarization process for Desert Locust are large and preventative management teams need to prospect all these areas to be efficient. A challenge of ongoing research is to be able to guide on where prospection surveys should be done depending on meteorological and vegetation conditions. An analysis of relationship between long-term prospection data of Desert Locust observations from 2005 to 2009 and spatio-temporal statistics of a vegetation index gathered by remote-sensing was conducted using multiple logistic regressions. The vegetation index was a composite Normalized Difference Vegetation Index (NDVI) given every 16 days and at 250m spatial resolution (MOD13Q1 from MODIS satellite). The statistics extracted from this index were: 1) spatial means at different scales around the prospection point, 2) relative differences of NDVI variation through time before the prospection and 3) large scale summary of vegetation quality. Identical statistics could potentially be computed for actual NDVI. By extrapolation of adequate logistic regression models, maps of probability of presence of locust could be constructed. This methodology should help in focusing prospection toward sensible parts of the gregarization areas at specific times.

Comparative study based on arthropods biodiversity indicators on paddy fields between integrated pest management and conventional technologies

Hagus Tarno[1], Gatot Mudjiono[2], Cicilia Nova Ratna Sari[3]

[1]University of Brawijaya, Indonesia, [2]University of Brawijaya, Indonesia, [3]University of Brawijaya, Indonesia

Agricultural ecosystem of paddy is an ecosystem that has a high arthropods biodiversity. Arthropods play the main role to the successfulness of agricultural ecosystem. Population and diversity of arthropods on paddy field is related to agronomic activities. The research was aimed to compare the impact of Integrated Pest Management (IPM) technology and conventional one on the paddy field based on arthropods biodiversity indicators. Research was conducted on paddy field located in Banyuwangi Regency, East Java, Indonesia. Both technologies were separated into two fields. To observe arthropods biodiversity upper ground, pan and pitfall traps were arranged systematically on field. In addition, soil samples were collected to evaluate below ground arthropods. The result showed that arthropods population on both IPM and conventional technology were fluctuated. Arthropods population increased in the vegetative stage and decreased in generative stage. Arthropod species numbers was higher on IPM technology field that conventional technology field. There were 118 species on IPM field and 103 species on conventional one. Total numbers of arthropods were higher on IPM field than conventional one. Equally community index between both fields was 0.009 and arthropods composition between both fields was similar. Dominancy index (Id), equitability level (E), diversity index (H`) and species richness (R) on IPM field was higher than conventional one.

Impact of mass-rearing and gamma radiation on thermal tolerance of *Eldana saccharina* Walker (Lepidoptera: Pyralidae).

Pride Mudavanhu[1], Des Conlong[2], Pia Addison[3]

[1]Stellenbosch University, South Africa, [2]South African Sugar Research Institute (SASRI), South Africa, [3]Stellenbosch University, South Africa

Exposure of insects to gamma radiation in order to induce sterility, and mass-rearing to produce the large quantities required for the Sterile Insect Technique (SIT) are some of the many factors that may influence thermal tolerance at species and population level. The effect of mass-rearing and different radiation doses on the thermal tolerance of adult Eldana saccharina moths was investigated. Critical thermal maximum (CTmax) and critical thermal minimum (CTmin) were determined and compared for both genders of E. saccharina from five different treatments namely wild, mass-reared and three sterility dosages (150, 200 and 250Gy). Results showed that both wild and mass-reared moths had similar high temperature tolerances (CTmax: 44.3, 44.5°C respectively) and these values were significantly higher than those of moths exposed to gamma radiation (43.8, 43.7, 43.5°C respectively). However, wild moths had a significantly higher tolerance to low temperature (CTmin) than mass-reared and sterile moths (3.7, 4.4, 4.8, 4.9, 6.1°C respectively). In both CTmax and CTmin trials interaction between gender and treatment was highly significant ($F(4, 90) = 4.19$, $p = 0.004$, $F(4, 90) = 3.71$, $p = 0.008$ respectively). These results demonstrate the importance of knowledge of laboratory domestication and irradiation on thermal tolerance of E. saccharina. In addition to these data, further information on potential geographic and seasonal distribution will contribute to a better understanding of the working of SIT as an area-wide control strategy under different agro-ecological conditions.

Biology of exotic predator *Cryptolaemus montrouzieri* Mulsant on an invasive mealybug, *Phenacoccus solenopsis* Tinsley under laboratory conditions.

Tajwer Sultana Syed
Sindh Agriculture University, Tandojam, Pakistan

Studies on biology of Cryptolaemus montrouzieri Mulsant were carried out on an invasive mealybug, Phenacoccus solenopsis Tinsley under laboratory at Entomology Department, Sindh Agriculture University, Tandojam, Pakistan. Egg incubation period of C. montrouzieri recorded in present study was 4.10±0.09 days (Mean±S.D). The incubation period remained almost same during the three generations of study. There were four larval instars; the duration of different instars was 1.47±0.39, 2.44±0.41, 3.29±0.58 and 3.33±0.48 days, respectively. There was some insignificant variation in larval stages in three generations. Pupal period of C. montrouzieri varied from 5.97±0.4 to 6.97±1.04 days during different generations. Female live longer than males ,the average life span of male varied from 21.8±6.16 to 25.6±4.47 days and that of female from 27.6±4.45 to 34.3±2.94 days. The fecundity of female C. montrouzieri varied from 113 to 399 eggs and 52.9 to 86.75% eggs were fertile. The pre-oviposition period of C. montrouzieri ranged between 8.5 to 9.8 days, oviposition period from 17.3 to 21.3 days and post-oviposition period from 1.9 to 4.4 days. The sex ratio of C. montrouzieri was almost 1:1 and females copulated 38.1 to 41.8 times during their adult life with the total duration of copulation ranging from 549.5 to 567.4 minutes .The duration of life cycle of C. montrouzieri varied from 48.46±4.12 to 56.24±2.76 days during different generations.

Keywords:*Cryptolaemus montrouzieri, biology, life cycle*

An empirical predictive model for the flight period of the ambrosia beetle *Platypus koryoensis* (Coleoptera: Platypodinae)

Youngwoo Nam[1], Dae-Sung Won[2], Jong-Kuk Kim[3], Sang-Hyun Koh[4], Won Il Choi[5]

[1]Korea Forest Research Institute, Republic of Korea, [2]Kangwon National University, Republic of Korea, [3]Korea Forest Research Institute, Republic of Korea, [4]Korea Forest Research Institute, Republic of Korea, [5]Korea Forest Research Institute, Republic of Korea

From 2007 to 2009, field studies were conducted in four Quercus mongolica forests in Korea to develop an empirical predictive model for the flight period of the ambrosia beetle Platypus koryoensis. The median date of the flight period (when 50% of beetles had flown) was estimated using a cumulative Weibull function based on the cumulative proportion of all adult trap catch in the field. The pooled cumulative proportion of flight period versus degree days was fitted by the Weibull function. The relationship was most significant using 5.9 °C as the baseline temperature for development, suggesting that this temperature was the lower developmental temperature threshold of P. koryoensis. The explanatory power of the model was 89% and the model was validated by field observations in 2011 at one of the sites. The influence of climate change on the flight period of this ambrosia beetle is briefly discussed.

Keywords:*climate change, degree-days, lower developmental temperature, phenology, Weibull function*

Estimates of pistachio yield losses caused in pistachio by pistachio psylla nymphs, *Agonoscena pistaciae* (Hemiptera: Psyllidae)

Mohammad Reza Hassani

Rafsanjan Branch, Islamic Azad University, Rafsanjan, Iran

The pistachio psylla, Agonoscena pistaciae Burckhardt and Lauterer is a major pest of pistachio trees, Pistacia vera L., through pistachio growing in Rafsanjan, Iran. The objective of this study was to determine the effect of different psylla nymph density and yield loss under field condition. Six different density levels of nymph (control, very low, low, median, high and very high density) established on pistachio trees by different insecticide dosages. The densities were monitored weekly by direct counting of nymphs per leaf from the median part of the canopy. Mean nymph density at each level was 0.6, 12.8, 32.5, 54.7, 83.8 and 114.7, nymphal-days, per leaf, respectively. After harvest, the yield loss was determined at each treatment. The yield loss was significantly affected by the number of nymphs. Mean weight of 1000 nuts in control, very low, low, median, high and very high density determined 834.4, 786.5, 741.7, 716.3, 625.6 and 477.4 g, respectively. Mean yield loss estimated 0, 47.9, 92.7, 118.1, 208.8 and 357 kg/h, respectively. Mean non-splitting determined 29, 34.2, 52.2, 59.4, 85.8 and 99.5%, respectively. Therefore, with increasing the nymph density, yield loss and percent of non-splitting increased, significantly. So, this insect is an economic pest of pistachio trees cultivar Ohadi in this area.

Impact of different pheromone traps installation on the capture and damage intensities of fruit fly species in various host crops

Muhammad Dildar Gogi[1], Muhammad Jalal Arif[2], Muhammad Ashfaq[3], Anjum Suhail[4], Sohail Ahmed[5], Muhammad Ahsan Khan[6], Muhammad Hamid Bashir[7], Zain Ul Abdin[8], Muhammad Arshad[9], Ali Anwar[10]

[1]University of Agriculture, Faisalabad, Pakistan, Pakistan, [2]University of Agriculture, Faisalabad, Pakistan, Pakistan, [3]University of Agriculture, Faisalabad, Pakistan, Pakistan, [4]University of Agriculture, Faisalabad, Pakistan, Pakistan, [5]University of Agriculture, Faisalabad, Pakistan, Pakistan, [6]University of Agriculture, Faisalabad, Pakistan, Pakistan, [7]University of Agriculture, Faisalabad, Pakistan, Pakistan, [8]University of Agriculture, Faisalabad, Pakistan, Pakistan, [9]University of Agriculture, Faisalabad, Pakistan, Pakistan, [10]University of Agriculture, Faisalabad, Pakistan, Pakistan

Fruit flies are the most important limiting factor in the quality production of fruits not only of orchard crops (guava, citrus, mango, banana, cocconuts, pine apple, ber, etc) but also of field crops (cucurbits, tomato, brinjal, pepper etc.). A complex nature of fruit flies trapping on different host plants as well as species specificity to various pheromones has been observed. The present studies were carried out to explore the species distribution and their damage intensities in various host plants like cucurbits, mango, guava and citrus and well as to investigate the species specificity of two pheromones (Methyl euginol and butanone acetate) at two places during 2010 and 2011. The fruit flies trapped in both types of pheromone traps were identified on the basis morphological keys. The fruits from treated (where pheromones were installed) and untreated fields and orchards of various host crops were collected at weekly intervals, observed for infestation in the laboratory and categorized into infested and unifested to calculate % fruit infestation. The infested fruits were placed on sterilized sand in plastic jars till the larval pupation. The pupae from sand were sieved and placed petridishes inside the incubator till adult emergence. The adult emerged were then identified and classified into different species. The fruit fly species and fruit infestation data obtained at different localities, host crops and pheromone traps were statistically analysed and the results are discussed.

Status of mango stone weevil, *Sternochetus mangiferae* Fab. (Curculionidae: Coleoptera) and its area-wide management leading to control and localized eradication in south India

Abraham Verghese[1], DK Nagaraju[2], Thippenahalli Narayanappa Shivananda[3], Manjunath R Hegde[4], Amrik Singh Sidhu[5]

[1]Indian Institute of Horticultural Research , India, [2]Indian Institute of Horticultural Research , India, [3]Indian Institute of Horticultural Research , India, [4]Indian Institute of Horticultural Research , India, [5]Indian Institute of Horticultural Research , India

The stone weevil, Sternochetus mangiferae Fab. (Coleoptera: Curculionidae) is a global quarantine pest and is serious in south India. The loss caused due to premature fruit drop and spoilage of pulp amounts to 30 to 40%. Ecological and management studies from 2001 to 2012 have helped in developing area-wide management strategies which is a combination of mechanical and insecticidal interventions, combining bark junction cleaning and timely spray intervention at oviposition of weevils when fruits have a diameter of 2-4 cm (poultry egg-size). The Integrated Pest Management have shown excellent results in south India. In Dharwar district of Karnataka, weevils have been controlled 100% in orchards of Alphonso. In Vellore district of Tamil Nadu the weevil infestation has come down from 40% to <2%. In a stretch of > 200 acres in Chitoor district of Andhra Pradesh the weevil has been eradicated since 2007. This IPM intervention has caught the attention of national and international quarantine agencies. This augurs well to mitigate risk and create pest free areas. It was found that by this intervention, farmers save about 25-40% of their mangoes, resulting in about 1000 kg more yield/acre. This gives an additional income of Rs 10000 to 12000 per acre (Rs 50 = 1US $). The cost benefit ratio was worked out to 1:12 In these areas, the numbers of processing industries have gone up by about 30% in the last five years, generating increased pulp export and rural employment. The support given by NABARD and ICAR is gratefully acknowledged.

Evaluation of some botanical extracts, adult food-baits, oviposition-baits, coloured egg-receptacles and cultural practices and their possible integration for IPM of melon fruit flies.

Muhammad Dildar Gogi[1], Muhammad Hamid Bashir[2], Muhammad Arshad[3], Zain ul Abdin[4], Muhammad Ahsan Khan[5]

[1]University of Agriculture, Faisalabad, Pakistan, Pakistan, [2]University of Agriculture, Faisalabad, Pakistan, Pakistan, [3]University of Agriculture, Faisalabad, Pakistan, Pakistan, [4]University of Agriculture, Faisalabad, Pakistan, Pakistan, [5]University of Agriculture, Faisalabad, Pakistan, Pakistan

Studies were carried to evaluate performance of aqueous extracts of some, adult food-baits, Oviposition-baits and egg-receptacles in the laboratory by olfactometer as well in the field on bitter gourd crop from 2006 to 2009; whereas, some cultural practices like sowing times, plant-to-plant distance, sowing methods and sanitary measures were evaluated in the field of bitter gourd crop. The results revealed that ginger, garlic and neem extracts (botanicals), GF-120 (adult Food-bait), yellow, white and orange colored Oviposition bait and egg-receptacles with water melon juice plus paste, Hang Sowing Method (HSM) and early sowing, with a plant to plant distance of 45 cm, performed better causing significant reduction in fruit fly infestation as well as yield losses/plant and significant increase in the number of marketable fruit/plants and marketable yield/plant. The most effective melon fruit flies management tactics, screened, through different experimentations, were integrated into different IPM-Models, which were evaluated under field condition. The result revealed that IPM-MODEL-2, IPM-MODEL-3, IPM-MODEL-4, IPM-MODEL-5, IPM-MODEL-6 and IPM-MODEL-7 were effective and economical resulting in marketable yield 6-7 times higher (CBR=1:6.2 to 1:7) than control (IPM-Model-8) and 2-3 times higher than conventional IPM-Model-1 (CBR=1:4.5). In conclusion, implementation of any of these IPM- Models in bitter gourd cropping system would reduce the infestation of melon fruit fly infestation and ensure the significant increase in bitter gourd yield with effective and economical cost-benefit ratio (CBR).

Alternative host plants of *Megalurothrips sjostedti* and *Frankliniella occidentalis* in French bean agroecosystems in Keyna

Linus Muthuri Gitonga
Karatina University College, Kenya

Sound management of agricultural pests requires knowledge of the pest, both on the target crop and the surrounding plant community. At the onset of flowering of French beans, there is rapid population build up of Megalurothrips sjostedti Trybom and Frankliniella occidentalis Pergande in the flowers. The extent to which co-existing thrips species utilize common resources is unknown in Kenya. Understanding the role of alternative hosts on population dynamics of thrips in French beans may lead to development of novel management strategies. Collections of alternative host plants were made at jkuat, kaguru and machakos Farmers'Training Centres. Presence of larvae and adults on various potential host plants were monitored by direct observation of flowers of wild and cultivated crops, up to 0.2km of the French bean fields. Flower samples were taken to the laboratory where adult thrips and larvae were extracted by dissecting the flowers. Adult thrips were identified under a binocular microscope. Larvae were removed and put in emergence cages, supplied with flowers of the plants from which they were extracted, and reared at room temperature until eclosion to adults. Many alternative hosts were found in flower after the rains, but also throughout the year. There were plants in flower at any given time of the year. Thrips, therefore, never lacked alternative hosts. Frankliniella occidentalis was found in more plant families relative

Biology and influential abiotic environmental variables for the beet leafhopper (*Circulifer tenellus*) in the Columbia Basin of Oregon and Washington

Alexzandra F. Murphy[1], Silvia I. Rondon[2], Andrew Jensen[3]

[1]Oregon State University, U.S.A., [2]Oregon State University, U.S.A., [3]Washington State Potato Commission, U.S.A.

The beet leafhopper, Circulifer tenellus Baker, is responsible for transmitting a phytoplasma that causes purple top disease in potatoes in the Columbia Basin of Oregon and Washington. This phytoplasma is referred to as beet leafhopper-transmitted virescence agent (BLTVA). Beet leafhoppers are a significant pest in many areas around the world, including much of Eurasia. The following study was designed to predict the population dynamics of the beet leafhopper in the Columbia Basin based on abiotic environmental factors. From 2006 through 2008, individual sticky card traps were placed at approximately 100 sites in Oregon and Washington. Beet leafhoppers collected by these traps were evaluated weekly. According to the 2006 through 2008 survey data, beet leafhopper populations typically peak in early June; a second peak occurs early to mid-October. Populations fluctuate significantly between years, and the abiotic environmental factors were analyzed to explain these extreme fluctuations. The correlations between weather, location and beet leafhopper populations will be discussed, as well as incorporated with beet leafhopper biology. Due to the inclusion of abiotic environmental factors, these results may provide useful information for other geographic locations.

The correlation between artificial night lightings and attraction response of insect

Heejo Lee[1], Yong-ki Kim[2], Youngdon Ju[3], Bosun Park[4], Minseon Kim[5], Xuan Vi Le[6], Mu-jie Qi[7], Ulziijargal Bayarsaikhan[8], Yang-Seop Bae[9]

[1]University of Incheon, Republic of Korea, [2]University of Incheon, Republic of Korea, [3]University of Incheon, Republic of Korea, [4]University of Incheon, Republic of Korea, [5]University of Incheon, Republic of Korea, [6]University of Incheon, Vietnam, [7]University of Incheon, Republic of Korea, [8]University of Incheon, Mongolla, [9]University of Incheon, Republic of Korea

The artificial night lighting gives the convenience of human life and it enables human nighttime activity. However, strong lamp causes the 'light pollution' because some are installed without special regulation and planning. The insects are specially attracted well by the lamp and cannot escape from the light and eventually killed by natural enemies or human's activities, naturally. It causes a decrease of population and it is very critical damage for the ecosystem because the insect is very important primary or secondary consumer on the food chain. This research will provide the foundational data and ground about the ecological effect by the light pollution. We try to find the attraction feature of insect that has high diversity compare with other groups, and predict the degree of disturbance to the ecosystem. We designed three main experiments. The experiments are about the attraction response of diverse artificial lightings have different brightness and colors, and the others are used a lot in human's life. We utilized light trap as attracting insect and counted the number of occupied insect around the each lamp. We measured the illumination and UV-A of all lamps, and tried to find the correlation. As a result, the lightings that attract much more number of insects have higher illumination and UV-A than the others, but there was no relationship with color. Also, the lightings have high UV-A and low illumination attract much more number of insects than low UV-A and high illumination.

A decade with *Solenopsis invicta* (Hymenoptera: Formicidae): Taiwan's experiences on fire ant control

Lekhnath Kafle[1], Cheng-Jen Shih[2]

[1]*National Taiwan University, Taiwan,* [2]*National Taiwan University, Taiwan*

Since its accidental invasion, red imported fire ant (Solenopsis invicta) was first observed in Taiwan in 2003 and until 2012, more than 50,000 ha land is already been infested. To prevent S. invicta from further spreads and subsequent damages, National Red Imported Fire Ant Control Center (NRIFACC) was established in 2004. Baits with either toxicants or insect growth regulators are the main control agents in Taiwan against S. invicta. To ensure the quality of fire ant treatments, GIS mapping of the delivery and tracking of the treatments were adopted. Similarly, sticky papers and pitfall traps are randomly placed to monitor the dose of fire ant baits applied. The potato chip based bait traps are used to confirm the presence or absence of fire ants at treated or suspected areas. The NRIFACC is assisting governmental agencies to formulate and execute the regulations to restrict the human-caused fire ant disseminations. NRIFACC organizes regular trainings/workshops to train local resource persons and use other mass media to create public awareness towards the fire ant management. Along with fire ant control efforts, numbers of scientific studies including development of water tolerant fire ant bait, exploration of native competitor ant species, nature based control materials, and population genetics are on the progress to facilitate the national fire ant control program. Recently developed new carrier based fire ant bait (T-bait) that tolerates water or high humidity could be a potential control tool for the Taiwan, China, Hong Kong and other areas.

Biological parameters and feeding efficiency of *Chrysoperla carnea* on different hosts

Jan Mari Muhammad
Sindh Agriculture University, Tandojam Pakistan, Pakistan

Study on the biological parameters and feeding efficiency of Chrysoperla carnea on different hosts was carried out in the laboratory of Plant Protection, S A U, Tando Jam. The results indicated that the pre-oviposition period was 7.8±1.17, 7.98±1.16, 7.4±1.39 and 6.9±1.51days on S. Cerealella, E. insulana, H. armigera and P. gossypiella respectively. Post-oviposition period of C. carnea lasted for 3.1±1.26, 5.3±2.63, 6.3±1.42, 8.1±1.36 and 4.3±1.15 days on S. cerealella, E. insulana, H. armigera and P. gossypiella, respectively. The mean duration of the first, second and third larval instars of C. carnea on different hosts was 3.1±0.056, 3±0.66 and 3.5±0.84 on S. cerealella, 3.25±0.58, 3.3±0.78, 4.15±0.63 on E. insulana, 3.89±1.12, 4.3±0.63, 3.5±0.45 on H. armigera and 3.1±0.68 on P. gossypiella 3.67± 0.65, 2.95± 0.45, 3.1± 0.68. The males lived for mean duration of 14.6±4.07, 35.8±1.78, 30.31±1.87 and 33.37±1.83, days on S. cerealella, E. insulana, H. armigera and P. gossypiella, respectively. The mean feeding percent per day of 1st, 2nd and 3rd instar larvae of C. carnea was 28.5, 56 and 87.5 percent eggs of S. cerealella, 29.25, 62.25 and 89.5 eggs of E. insulana, 24.25, 63 and 86.25 eggs of H. armigera and 29.25, 59 and 90.5 eggs of P. gossypiella. It also observed that the third instar was most voracious feeder. From data it was concluded that the predator can be reared on all the five hosts. Therefore, S. cerealella eggs are the ideal food for rearing the predator because of its availability round the year.

Morphometrics and Integrated control of *Macrotermes bellicosus* (Isoptera: Termitidae) on newly established cocoa plantation in Ibadan, Nigeria

Joseph Chuks Anikwe[1], Feyisara Abiodun Okelana[2], Kehinde Kemabonta[3], Winifred Ayinke Makanjuola[4]

[1]University of Lagos, Nigeria, [2]Cocoa Research Institute of Nigeria, Nigeria, [3]University of Lagos, Nigeria, [4]University of Lagos, Nigeria

An unprecedented outbreak of termite infestation was observed at the Cocoa Research Institute of Nigeria Headquarters (CRIN), Ibadan during the 2005/06 cocoa seasons in which several newly established and old plantations were put under threat. An integrated pest management (IPM) approach which comprised physical, cultural and chemical methods was put in place to control the infestation and damage caused by this pest in order to provide a healthy environment for the growth of the newly established cocoa plants in the field. In a two hectare plantation consisting of about two thousand and eighty (2, 080) young cocoa plants, every stand showed symptoms of attack by termites while a total of 176 termite mounds were counted. The characteristics and morphology of mounds as well as the different castes of termites were described and reported. The average circumference of mound measured was 6.1 meters with a range of 3.6 to 8.6 meters while the mean height was 1.59 meters with a range of 0.7 to 2.8 meters. The most numerous and smallest in size of the castes were the workers with a body length of 1.24cm and body width of 0.4cm. Both physical and chemical treatments were carried out on all mounds while dry and decomposing logs, stems and fallen branches were removed from the plantation for use as firewood. One year after treatment, only 415 (20%) young cocoa stands which could not survive previous season attacks, were replanted. The plantation was subsequently monitored for two seasons for termite infestation.

Distribution of potato leafminer fly, *Liriomyza huidobrensis* (Blanchard) (Diptera: Agromyzidae) and its damage in potato crops in Nepal

Rameswor Maharjan[1], Chuleui Jung[2], Marc Sporleder[3], Jurgen Kroshel[4]

[1]Andong National University, Republic of Korea, [2]Andong National University, Republic of Korea, [3]International Potato Center, Peru, [4]International Potato Center, Peru

Potato leafminer fly, Liriomyza huidobrensis (Diptera: Agromyzidae), is an economically important pest of potato and ornamental plants in Nepal. Though pesticide application is common control practice against this pest, pesticide resistant of this pest stalls proper management. Distribution and damage assessment were conducted in major potato growing districts (Kavre, Lalitpur, Kathmandu, Bhaktapur, Makwanpur and Sindhupalchowk) of Nepal during 2009 and 2010. A total of 199 farmers fields were surveyed from the six districts. Also, 10 fields were assessed for damage in each district by randomly selecting 10 potato plants from each field. To quantify level of damage, plant samples were taken to laboratory. Damage level was compared according to location, altitude, variety, and cropping systems. Distribution of the pest was found mostly concentrated on the mid-hill region with high level of infestation. The damage level varied among the districts. Highest damage was recorded in Lalitpur (1332msl) district and least was in Sindhupalchowk district (2301msl) in both years. No parasitism was recorded in high altitude (2301msl). 'Cardinal' and 'Lal-gulab' potato varieties showed highest infestation (45%) while 'Rosita' showed the lowest (4.25%). Among cropping systems, in maize-potato-vegetable system showed higher damage (46.15%) followed by rice-potato-potato system and the root crop-fallow-potato system showed least.

Area wide implementation of integrated pest management in India for cauliflower cultivated in rainy season

Desh Bandhu Ahuja[1], M. N. Bhat[2], R. V. Singh[3]

[1]NCIPM LBS Building PUSA Campus New Delhi, India, [2]NCIPM LBS Building PUSA Campus New Delhi, India, [3]NCIPM LBS Building PUSA Campus New Delhi, India

Cauliflower occupies fifth position in total production of 133.74 million tonnes of vegetables in India. Due to genetic advancement and improvement in production system, cauliflower can be cultivated throughout the years which were earlier confined to winter season only. It has resulted in quantum jump in earnings of farmers, but also has attracted a large variety of pests that are potential threat to its cultivation. In order to sustain its production farmers resort to 10-12 applications of pesticides over a period of four months to prevent the damage due to the potential pests such as Spodoptera litura, Helulla undalis, Pythium sp and Alternaria brassicae and A. brassicola in the rainy season from month of June to November. To address the problem of over use of pesticide and restore sustainable cultivation of cauliflower, integrated pest management technology comprising soil solarisation, raised bed method of developing nursery, application of Trichoderma harzianum to soil through FYM, pest monitoring through sex pheromone trapping, scouting of pest damage, collection of egg masses of S. litura, plucking of pests infested leaves, need based application of reduced risk pesticides and monitoring of insecticide resistance in S.litura was developed and validated and popularize in farmers participatory mode for state of Haryana and Rajasthan of India. The implementation of IPM technology envisaged higher economic returns, lower pest incidence and cost of plant protection and higher natural enemies' population. It can also be implemented in other states of India having similar pattern of cauliflower cultivation with similar pest problems.

Use of *Tithonia diversifolia* and *Metarhizium anisopliae* in a lure-and-kill approach for thrips management

Saliou Niassy[1], Nguya Kalemba Maniania[2], Ayuka T. Fombong[3], Baldwyn Torto[4], Sevgan Subramanian[5], Sunday Ekesi[6]

[1]University of Pretoria, South Africa, [2]International Centre of Insect Physiology and Ecology (icipe), Kenya, [3]International Centre of Insect Physiology and Ecology (icipe), Kenya, [4]International Centre of Insect Physiology and Ecology (icipe), Kenya, [5]International Centre of Insect Physiology and Ecology (icipe), Kenya, [6]International Centre of Insect Physiology and Ecology (icipe), Kenya

The attraction of the thrips Frankliniella occidentalis to commercial thrips kairomone LUREM-TR and natural lure from flower heads of Tithonia diversifolia was studied in the field. Blue sticky trap, preferred thrips visual cue, was also included in the study. Blue sticky traps baited with flower heads of T. diversifolia captured three-fold more F. occidentalis than blue sticky traps (control). However, traps baited with kairomone LUREM-TR attracted significantly more thrips than traps baited with T. diversifolia flower heads and the control. There were no significant differences in thrips captures between traps baited with T. diversifolia and the control due to the neighbouring effects of LUREM-TR. We also investigated the possibility of integrating M. anisopliae with lures in autodissemination approach. In laboratory assays, organic extracts of the flower heads of T. diversifolia were compatible with the fungus than water extracts while LUREM-TR completely inhibited conidia of the M. anisopliae. Conidial acquisition and mortality of thrips attracted to the autoinoculation device baited either with flower heads of T. diversifolia or LUREM-TR were not significantly different between the treatments sin greenhouse experiments. The potential of using T. diversifoliaflower heads as an alternative kairomone source for a lure and kill strategy for thrips management is discussed.

The effect of certain watermelon varieties on the biology of *Aphis gossypii* Glover (Hemiptera: Aphididae)

Yunus Bayram[1], Erol Bayhan[2]

[1]Plant Protection Research Station in Diyarbakir,TURKEY, Turkey, [2]Plant Protection Department University of Dicle in Diyarbakir, TURKEY, Turkey

The development, reproduction, and population growth parameters of the melon aphid, Aphis gossypii (Glover), on four watermelon varieties were evaluated in climatic room and growth chambers. The watermelon varieties were Crimson Sweet, Crimson Tide F1, Galactica, and Surme. Significant differences in the biology of Aphis gossypii were observed. The highest fecundity was recorded on Galactica (58.97 offspring/female), followed by Crimson Tide F1 (57.80 offspring/female), Surme (57.25 offspring/female) and Crimson Sweet (57.03 offspring/female). The highest net reproductive rate was observed on Crimson Tide F1 (22.40 offspring), while the lowest was on Surme (18.61 offspring).

Evaluating alternatives to conventional pest control in Benin

Codjo Euloge Togbe[1], Rein Haagsma[2], Elisabeth ZANNOU[3], Gualbert Gbehounou[4], Jean Marcel Deguenon[5], Simplice Vodouhe[6], Dansou Kossou[7], Arnold van Huis[8]

[1]Wageningen University, Benin, [2]Wageningen University, Netherlands, [3]Universite d'Abomey-Calavi, Benin, [4]Institut National des Recherches Agricoles du Benin, Benin, [5]Universite d'Abomey-Calavi, Benin, [6]Universite d'Abomey-Calavi, Benin, [7]Universite d'Abomey Calavi, Benin, [8]Wageningen University, Netherlands

Efficacy of Neem oil (Azadirachta indica) alone and, depending on the pest, combining with the entomopathogenic fungus Beauveria bassiana formulation Bb11, both threshold applied for controlling cotton pests, was compared to conventional calendar-based spraying with synthetic pesticides and the "Lutte Etagee Ciblee (LEC) strategy, consisting of calendar-based spraying (half dose) followed by threshold application of synthetic pesticides. The experiment was carried out with farmers in three cotton agro-ecological zones differing in rainfall, pest prevalence, and farmer practices. The neem oil, and neem oil-Bb11 treatments required 2 to 6 treatments, while conventional and LEC received 6 to 8 treatments. Percentage damaged bolls in plots receiving the neem oil and neem oil-Bb11 treatment was higher than in those having the conventional and LEC treatments, resulting in yields being 25 and 39% lower, respectively, while in one agro-ecological zone with low rainfall there was no difference. Yields in the biopesticide plots were 26-42% higher than in plots without having received pesticides, while in the conventional and LEC plots they were 44-59% higher. Natural enemy incidence was highest in the control without using pesticides and in the biopesticide plots. Overall, the LEC regime scored best, both in yield and profitability but the specific pesticides required are not made available on the market. Using the entomopathogen Bb11 and neem oil avoid many problems associated with synthetic pesticide use, but their efficacy need to be enhanced by improved formulation or combining it with other pesticides in order to become a viable alternative.

Effects of the essential oils of *Lavandula angustifolia* Mill and *Zataria multiflora* Boiss on reproduction and F1 population of *Callosobruchus maculatus* (F.)

Gholamhossein Moravvej[1], Zahra Golestani Kalat[2]

[1]*Ferdowsi University of Mashhad, Iran,* [2]*Ferdowsi University of Mashhad, Iran*

Inhibitory effects of L. angustifolia and Z. multiflora essential oils were evaluated on reproduction and F1 progeny production of C. maculatus. Insects culture and bioassays were conducted at 30 ±1ºC, 60±5% RH and dark condition. Essential oils were taken by hydrodistilation. The results indicated that there was a negative and significant linear relationship between reproduction of beetles and oil concentration. Similar relationships was found between F1 progeny and oil concentration. Comparison of regression slopes showed that L. angustifolia oil was more effective than Z. multiflora oil on reproduction and F1 progeny population. The essential oils analysis by GC-MS showed that the main compounds of L. angustifolia oil were linalool, 1,8-cineol, rosefuran epoxide, menthone, isomenthol and dihydro carvone (trans) and those of Z. multiflora oil were thymol, linalool and p-cymene. The results indicated that these two essential oils especially L. angustifolia oil might be suitable alternatives for stored products protection against C. maculatus.

Keywords:*Essential oils, F1 progeny reduction L. angustifolia, reproduction inhibitory, Z. multiflora.*

Impact of *Lantana camara* leaf extracts on development and reproductive bioactivities of *Dysdercus koenigii*

Kamal Kumar Gupta[1], Sunil Kayesth[2]

[1]*Deshbandhu College, University of Delhi, India,* [2]*Deshbandhu College, University of Delhi, India*

Development and reproductive bioactivities of Dysdercus koenigii as modified by the leaf extracts of Lantana camara were evaluated. Fifth instar nymphs of Dysdercus were treated with four concentrations of ethanol extract and hexane extract prepared from leaves of Lantana camara. Dysdercus exhibited significant alteration in their survival, longevity, development and reproduction when treated with ethanol extract. A significantly higher mortality was observed in the nymphs and adults when treated with higher dose of the extract. At lower concentration, the ethanol extract of Lantana influenced development and reproduction in Dysdercus. Hence the treated insects exhibited delayed moulting, supranumery instars and abnormal moulting. The adults emerged from the treated fifth instar nymph were characterized by wings deformities, malformed proboscis and shrunken body. The developmental aberrations were dose related and also the effects were more pronounced when the extract was applied to newly emerged fifth instar. The ethanol extract of Lantana also affect the reproductive behavior, fecundity and fertility of Dysdercus. This resulted in reduction in the number of egg batches, number of eggs in each egg batch and total number of eggs laid by the female in its entire life span. More than 50% of eggs laid by these females were sterile. The hexane extract of Lantana leaves had more pronounced effect on the mating behavior of Dysdercus. Consequently, treated males showed lesser number of mounting attempts and delayed mating and decreased percent successful mating. Possible role of JH mimicking moleculles present in Lantana in development and reproduction of Dysdercus was discussed.

Keywords:*Dysdercus, Lantana, Development, Reproduction*

Green synthesis of silver nanoparticles (AgNps) and azadirachtin for the control of Asian palm weevil *Rhynchophorus ferrugineus*. (Olivier) (Coleoptera: Curculionidae)

Duraisamy Amerasan[1], Kadarkarai Murugan[2], Jayapal Subramaniam[3], Kalimuthu Kovendan[4], Palanisamy Mahesh kumar[5], Chellasamy Panneerselvam[6]

[1]Bharathiar university, India, [2]Bharathiar university, India, [3]Bharathiar university, India, [4]Bharathiar university, India, [5]Bharathiar university, India, [6]Bharathiar university, India

Green chemistry is a design, development, implementation of chemical products and processes to reduce or eliminate the use and generation of substances hazardous to human health and environment. The use of environmentally benign materials like plant leaf extract, bacteria and fungi for the synthesis of silver nanoparticles offers numerous benefits of eco-friendliness and compatibility for pharmaceutical and biological applications of Neem tree, Azadirachta indica, A. Juss. (Meliaceae), has been widely studied due to the presence of a great number of compounds with insecticidal properties and that are effective on several pest species. The invasive red palm weevil, R. ferrugineus (Olivier) (Coleoptera: Curculionidae), has become the major pest of palms trees in India. Economically speaking of the 40 millions coconut palms was affected by the pest which accounts to 200,000 palms every year in India. In the present investigation under the laboratory condition R. ferrugineus larvae, pupae and adult was treated with azadirachtin and synthesized AgNps . After 48 hrs, Larval, pupal and adult mortality was determined. AgNps shows highest larval mortality (99.3%), pupicidal (78.3 %) and adulticidal (69%) activity against R. ferrugineus in all the tested concentrations (3, 6 and 10 ppm) than the azadirachtin treatment. Therefore, the present investigation clearly exhibit that AgNps could serve as a potential of highest mortality rate against the R. ferrugineus larvae, pupae and adult in laboratory conditions.

Keywords:*Silver nanoparticles (AgNps), Azadirachtin, Rhynchophorus ferrugineus*

Screening of some citrus oils against two strains of Khapra beetle (*Trogoderma granarium*) Everts (Coleoptera: Dermestidae) collected from Vehari and Faisalabad districts of Punjab, Pakistan

Mansoor Ul Hasan[1], Muhammad Sagheer[2], Qurban Ali[3], Imran Faraz[4]

[1]University of Agriculture Faisalabad, Pakistan, Pakistan, [2]University of Agriculture Faisalabad, Pakistan, Pakistan, [3]University of Agriculture Faisalabad, Pakistan, Pakistan, [4]University of Agriculture Faisalabad, Pakistan, Pakistan

Mansoor ul Hasan, Muhammad Sagheer, Qurban Ali, Imran Faraz Department of Agricultural Entomology, University of Agriculture Faisalabad, Pakistan E.mail: mansoorsahi2000@yahoo.com In the present study, an attempt was made to examine the effects of essential oils of four citrus species (Citrus paradisi, Citrus sinensis, Citrus aurantium and Citrus reticulata) on two different strains (Faisalabad and Vehari) of T. granarium. Grubs of T. granarium were exposed for 3, 6 and 9 days to grains treated with 2, 4 and 8% concentrations of citrus peel essential oil under laboratory conditions. At concentration of 8% C. aurantium essential oils were highly effective against T. granarium than other citrus species with respect to percent mortality (27.30%), followed by C. reticulate (26.65%), C. sinensis (22.36%) and C. paradisi (20.00%). From data it has been observed that Faisalabad strain is susceptible than Vehari strain against T. granarium. At 8% concentration F1 progeny failed completely to develop in case of C. sinensis. Data regarding grain loss caused by T. granarium showes that minimum grain loss occurred in case of C. aurantium treated grains, followed by C. paradisi, C. sinensis and C. reticulate. It could be concluded that citrus essential oils possess excellent insecticidal, growth inhibition and antifeedant activity against T. granarium.

Keywords:*Citrus species, essential oils, mortality, grain loss, T. granarium*

Bio-efficacy of botanicals and bio-pesticides in the management of defoliator complex of *Gloriosa superba* (Linnaeus)

Mariappan Suganthy[1], Periyaswamy Sakthivel[2]

[1]Tamil Nadu Agricultural University, Coimbatore, Tamil Nadu, India, [2]Tamil Nadu Agricultural University, Coimbatore, Tamil Nadu, India

Gloriosa superba is a medicinal plant of immense value in the traditional systems of Indian medicine. Seeds contain colchicines and thiocolchicocide and possess many medicinal and curative properties. G. superba is devasted by defoliators like Polytela gloriosae, Plusia signata and Spodoptera litura. Field experiments were carried out at the Department of Medicinal and Aromatic Crops, Tamil Nadu Agricultural University, Coimbatore, Tamil Nadu, India and in the farmers' holdings to study the field efficacy of bio-pesticides and botanicals for the management of above defoliators infesting G. superba. Results of the experiments revealed that among the treatments, flavonoids at one ml per litre of water (Max Ranger-D2®) recorded superiority in the management of defoliators starting from third day after foliar spray and found to be statistically on par with standard chemical check, quinalphos at 2 ml per litre. Pungamia pinnata seed oil 3 per cent was next in the order of efficacy, followed by azadirachtin 1 per cent and neem seed kernel extract 5 per cent. Efficacy of Bacillus thuringiensis @ 250 larval equivalents was realized only at seven days after treatment and persisted even after 14 days of second spray. At 14 days after treatment, Bt was second in the order of efficacy next to chemical pesticides and flavonoids. From the results of both the field trials, flavonoids are adjudged and recommended as the best alternative to chemical pesticides in gloriosa ecosystem and can be recommended as one of the components in organic pest management.

Respiratory toxicity of *Thuja orientalis* on different life stages of *Tribolium castaneum*

Monireh Taeed[1], Rana Pooraiiouby[2], Nouraddin Shayesteh[3], Shahzad Iranipour[4]

[1]Tabriz Branch, Islamic Azad University, Tabriz, Iran., Iran, [2]Tabriz Branch, Islamic Azad University, Tabriz, Iran., Iran, [3]Islamic Azad University, Mahabad Branch, Iran, [4]Tabriz Branch, Islamic Azad University, Tabriz, Iran., Iran

Tribolium castaneum is one of the most important storage pests which cause significant losses on stored products. Utilization of chemicals has unfavorable effects on flour and makes it unusable. Therefore it is necessary to substitute the conventional chemicals with appropriate alternatives. Since plant extracts do not have uncomplimentary effects, hence seem to be appropriate alternatives for chemicals. In this research, the respiratory toxicity of Thuja orientalis extracts has been evaluated against eggs, larvae and adults of Tribolium castaneum. In this regard, essence of Thuja orientalis fresh leaves have been extracted with clevenger apparatus and hydro distillation method, and its toxicity have been tested on 1-7 days old adults, 14-16 days old larvae and 1-3 days old eggs of Tribolium castaneum in 25±1°C temperature and 70±5% relative humidity and dark conditions with 10-83 µl/350 ml air with 4 repetition. Experiments revealed that the mortality rate considerably increases in higher extract's concentrations and exposure times. Additionally results showed different life stages of Tribolium castaneum had diverse susceptibilities to the extract as more susceptibility of the adults compared to that of eggs and larvae. The calculated LC50 of this study in 24 hours exposure time was 18.81± 2.15 µl/350 ml airs for adults, 29.48± 1.44 µl/350 ml airs for larvae and 40.02± 1.48 µl/350 ml airs for eggs. These Results indicated that the extracts of Thuja orientalis could be introduced as a suitable alternative to chemicals.

Evaluation of *Solenostemma argel* extracts for their potential larvicidal activities against *Anopheles arabiensis* Patton (Diptera: Culicidae)

Amal Elsayed Edriss[1], Abdalla Abdelrahim Satti[2], Zuhair Alfadil Alabjar[3]

[1]Sudan Academy of Science, Sudan, [2]Sudan Academy of Science, Sudan, [3]Sudan Academy of Science, Sudan

Abstract: Among the prevalent mosquito species in Africa Anopheles arabiensis is the important malaria vector distributed in most countries. The main control tactics adopted depend largely on the application of synthetic chemicals. However, the socio-economic and environmental drawbacks of these chemicals are well known in everywhere. Therefore, this work was proposed to study the occurrence of A. arabiensis in central semi arid region of Sudan, and to evaluate different extracts of Solenostemma argel on its control. Leaves and seeds of the plant were extracted using water and organic solvents (viz., petroleum ether and ethanol), and their phytochemical constituents were analyzed. Bioassays of such extracts were conducted against the 4th instar larvae of the mosquito, where the mortality and residual effects were compared. The results revealed that the relative occurrence of A. arabiensis were higher around the River Nile. The chemical constituents of the tested extracts showed variable levels of secondary metabolites, i.e., alkaloids, saponins, flavones, flavonoids, amino acids, triterpenoids and sterols. The highest mortality percent (90%) was achieved by the seeds petroleum ether extract (LD50 1000ppm), which was comparable with that of the standard insecticides (Malathion and Abate) used. This extract also gave the best residual activity after one month. However, the mortality means of different botanical treatments increased with increasing concentrations and time of exposure. In conclusion, the findings proved the potent insecticidal activity of S. argel against A. arabiensis, and suggested more studies to be utilized commercially as natural mosquito larvicide.

Comparative assessment of insecticidal effect of some wood treated with plant extract on termite

Sunday Adeniyi Adeduntan[1], Johnson Adeyinka Olusola[2], Adeola Razaq Jimoh[3]

[1]The Federal University of Technology, Akure Nigeria, Nigeria, [2]Federal University of Technology Akure, Nigeria, Nigeria, [3]The Polytechnic Ibadan, Saki campus, Nigeria

This study compares the insecticidal effect of some plant extracts on some wood species against termite attack. Five different wood species were used for the study (Gmelina arborea, Sterculia rhinopetala, Cordia millenii, Cola gigantea, and Ceiba petandra. Neem seed, Liquefied biomass and undiluted macerated Neem leaves were used to compare the most effective plant material on the wood species on field test. The wood samples were oven dried, cold soaked for 24hours and conditioned for 48 hours and randomly placed in termiterium. Evaluations of termite attack on wood samples were carried out bi-weekly for twelve weeks. Ceiba petandra (89.43%) treated with Liquefied biomass recorded the highest mean percentage absorption, followed by C. petandra treated by neem seed (64.09%) and one treated by neem leaves (56.36%) had the least absorption. Ceiba petandra treated wood had the highest value (2663.93 g/cm3) for retention followed by wood treated with liquefied biomass, while wood species treated with neem seed extract had (6.45 g/cm3) and those of neem leaves (178.65 g/cm3). The least percentage weight loss was recorded in Gmelina arborea, liquefied biomass treated wood had (87.43%) followed by neem seed treated wood (39.21%) while the highest weight loss was recorded in neem leaves (54.80%) treated wood. There was little attack on the treated wood species but all the untreated samples were destroyed. Termite attack on wood treated with liquefied biomass was significantly lower compared with other wood species treated with other plant materials.

Toxicological and repellent impact of essential oils of *Citrulus colocynthus, Citrus pardesi, Solanum nigrum* and *Cuminum cymintion* against *Trogoderma granarium* (Everts) (Coleoptera: Dermestidae)

Muhammad Sagheer[1], Mansoor ul Hasan[2], Ahsan Ullah Saleem[3], Bilal Saeed Khan[4], Fawad Zafar Ahmad Khan[5], Kazam Ali[6]

[1]University of Agriculture, Faisalabad, Pakistan, Pakistan, [2]University of Agriculture, Faisalabad, Pakistan, Pakistan, [3]University of Agriculture, Faisalabad, Pakistan, Pakistan, [4]University of Agriculture, Faisalabad, Pakistan, Pakistan, [5]University of Agriculture, Faisalabad, Pakistan, Pakistan, [6]University of Agriculture, Faisalabad, Pakistan, Pakistan

Toxicological and repellent effects of essential oils obtained from Citrulus colocynthus, Citrus pardesi, Solanum nigrum and Cuminum cymintion were evaluated, under laboratory conditions, against Trogoderma granarium (Everts), a serious pests of stored cereals. Essential oils were extracted using acetone solvent in Soxhlet's apparatus. Three concentrations viz., 5, 10 and 15% of each plant extract were used for both bioassays. Data of percent morality was observed after three different post treatment intervals viz., 3, 5 and 7 days. The results revealed that all the treatments differed significantly from one another at all the concentration levels of the plant extracts and at all the post treatment intervals. The application of oil extract of C. Colocynthus showed maximum mortality of the pest at all the concentration levels followed by Solanum nigrum, Citrus pardesi and Cuminum cymintion. The exposure period of 7 days showed maximum mortality of the pest i.e. 23.75% in C. colocynthus followed by 14.17, 12.92 and 12.08 in oil extract of S. nigrum, Citrus pardesi and Cuminum cymintion, respectively. From the results it was found that C. colocynthus at maximum concentration and longer exposure period found to be the most effective as compared to other oil extracts of botanical origins. Experiments were also conducted to evaluate the repellent effects of these plant extracts. Results reveals that highest repellency (82.66%) was observed against C. Colocynthus followed by C. pardesi (76.33%), C. cymintum (68.36%) and S. nigrum (62.66%).

Deep mining of transcriptome data of four Lepidoptera pests

Zhang Zan[1], Xue Juan[2], Li Fei[3]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China

Chilo suppressalis, Scirpophaga incertulas, Cnaphalocrocis medinalis and Spodoptera exigua are important Lepidoptera pests, which cause great reduction in rice production. However, the gene data of these pests are scarce. We sequenced the transcriptome of four Lepidoptera pests using Illumina Solexa technique. The qualified reads were assembled into contigs by the software Trinity. In total, there are 69977, 64069, 73284, 31414 contigs, of which 27,347, 28,582, 36,802 and 18,592 contigs were annotated as protein-coding transcripts for C. suppressalis, S. incertulas, C. medinalis and S. exigua, separately. The similarities of nucleotide and protein sequences between abovementioned pests and Bombyx mori were analyzed. The results indicated that the C. suppressalis and S. incertulas are the most close species among the five insects. Though S. incertulas is monophagous whereas C. suppressalis is ploryphagous, S. incertulas has the more digestive enzyme transcripts than C. suppressalis. The reason is worthy of further investigations. It is possible that there are some symbiotic bacterias which enabled C. suppressalis to digest more plants. We also found some insecticide resistance genes including acetylcholine receptor, acetylcholinesterase, glutathione S-transferase, p450, and ryanodine receptors in each transcriptome data, which can be used to further analysis.

Resistance characteristics of different *Brassica* species to mustard aphid, *Lipaphis erysimi* Kalt. (Hom.: Aphididae)

Gholamhossein Moravvej[1], Mojtaba Hosseini[2], Samaneh Roudposhti[3]

[1]Ferdowsi University of Mashhad, Iran, [2]Ferdowsi University of Mashhad, Iran, [3]Ferdowsi University of Mashhad, Iran

The mustard aphid, Lipaphis erysimi is one of the most severe pests of canola in Iran and other tropical regions in the world. Three species of Brassica including B. napus (cv. Licord, Elite, Okapi, Hyola 401, and RGS003), B. juncea (cv. Land race) and B. rapa (cv. Park land) were screened for antixenotic and antibiotic resistance to L. erysimi under greenhouse condition at 25±2℃, 60±5% r.h. and a photoperiod of 16:8 h. (L: D). The results of antixenosis test indicated that density of L. erysimi was significantly different on canola cultivars at different hour counting ($P < 0.05$ and $P < 0.01$ after 48 and 72 h, respectively). Aphid density on Elite, Okapi, and RGS003 cultivars was significantly higher than that on other cultivars. In antibiosis test, significant differences were detected among canola cultivars in aphid life-table parameters including intrinsic rate of increase (rm) ($P < 0.05$), net reproductive rate (Ro) ($P < 0.05$), mean generation time (T) ($P< 0.05$) and finite rate of increase (λ) ($P < 0.05$) with the exception of population doubling time (DT) ($P > 0.05$). The aphids had the highest rm on Land race cultivar (0.324 female/female/generation) and lowest on Elite (0.278 female/female/generation). Our results suggested the cultivars Elite, Okapi and RGS003 as the least susceptible host for L. erysimi. The resistant canola cultivars identified in the present study could be used for the management control of mustard aphid.

Adaptation of the brown planthopper to a highly resistant rice variety PTB33

Jedeliza Ferrater[1], Peter de Jong[2], Marcel Dicke[3], Finbarr Horgan[4]

[1]International Rice Research Institute, Philippines, [2]Wageningen University and Research Center, Netherlands, [3]Wageningen University and Research Center, Netherlands, [4]International Rice Research Institute, Philippines

The Indian rice variety PTB33 is one of the most resistant to the brown planthopper (BPH), Nilaparvata lugens (Stal), and has been used extensively in breeding programs aimed at increasing rice resistance to biotic stresses. The sources of resistance in PTB33 are still not fully understood, but it appears that the variety may contain several resistance genes (bph2, Bph3, Bph17), thus contributing to its durability. We examined the resistance of PTB33 against six BPH populations from the Philippines. Planthopper weight-gain, longevity and egg-laying were lower on PTB33 than on the susceptible standard TN1. We artificially selected for virulence in all six populations by rearing planthoppers on the resistant variety over 20 generations. Adapted planthoppers had increased survival, longevity and reproductive output when compared to non-adapted colonies. We then screened, using the adapted and non-adapted BPH colonies, 30 differential rice lines with different BPH genes for their effects on planthoppers. The results were used to determine likely or analogous BPH resistance genes present in PTB33. We also monitored sequentially the abundance of endosymbionts in the pre-adapted and adapted colonies to examine possible relations between endosymbionts and planthopper virulence.

RNA interference in the migraltory locust

Xianhui Wang[1], Yuan Luo[2], Le Kang[3]

[1]Institute of Zoology, Chinese Academy of Sciences, China, [2]Institute of Zoology, Chinese Academy of Sciences, China, [3]Institute of Zoology, Chinese Academy of Sciences, China

Locusts are one of the most destructive agricultural pests in the world, causing considerable economic and ecological damage. They are also an important physiological model, as they exhibit responses to environment that manifest themselves as phenotypic changes in behavior, color, metabolism, development, and morphology, known as locust phase polyphenism. We observed that the locust has pronounced sensitive systemic RNAi in response to dsRNA injection for both broadly-expressed as well as tissue-specific genes but has no senstive response to dsRNA feeding. The evidence from in vivo loss-of-function and in vitro experiments suggested that the LmSID-1 gene was not required for systemic dsRNA uptake and spread, implying the existence of alternative mechanisms underlying insect systemic RNAi, which may be different from Caenorhabditis elegans or mammals.

Screening of lethal genes for feeding RNAi by leaf disc-mediated systematic delivery in *Tetranychus urticae*

Deok Ho Kwon[1], Ji Hyun Park[2], Si Hyeock Lee[3]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Seoul National University, Republic of Korea

The screening of effective lethal genes was conducted via the systemic delivery of dsRNA for the RNAi-based management of Tetranychus urticae. Four candidate genes (coatomer protein complex, T-COP; M1 metalloprotease, T-M1MP; Ribosomal protein S4, T-RPS4; A subunit of V-ATPase, T-VATPase) with a reference genes (EGFP) were tested for the experiment. The permeated dsRNA to the leaf disc (ca. 30 mm diameter) was detected at 12 h after treatment, indicating that dsRNA could move through veins on the leaf. In the evaluation of mortality, the T-COPB, T-RPS4 and T-VATPase exerted higher toxicities at 72 hour after treatment among four dsRNA tested. Gene knockdown corresponding four dsRNA were confirmed by qPCR, suggesting that the dsRNA could suppress the target mRNA through feeding dsRNA. In summary, the dsRNA delivery via leaf disc was effective in screening lethal genes and some genes, such as T-COP, T-M1MP, T-RPS4 and T-VATPase, can be applicable for establishing a RNAi-based control system against T. urticae.

Insect resistance to Bt plants: Time to start paying attention?

Andrei Alyokhin
University of Maine, U.S.A.

Bt plants provide a valuable and often environmentally friendly tool for managing insect pests. Growers of non-Bt corn are currently benefiting from area-wide suppression of insect pests by Bt corn, while organic corn growers use Bt sprays to control the same pests. Failure of Bt corn to control target pests is likely to encourage the use of less environmentally benign chemical insecticides, thus increasing health risks to the general population. Clearly, the preservation of this technology is important for people far beyond the producers of Bt corn. Unfortunately, recent field failures of Bt corn due to the damage caused by resistant rootworms confirm that it is potentially vulnerable to insecticide resistance. Yet, current resistant management plans are based on several somewhat questionable assumptions, which should be further scrutinized by the scientific community.

Sources of resistance in wheat to sunn pest (*Eurygaster integriceps* Puton) identified using the focused identification of germplasm strategy (FIGS)

Mustapha El Bouhssini[1], Ken Street[2], Abdallah Bari[3], Ahmed Amri[4], Francis Ogbonnaya[5], Miloudi Nachit[6], Mesut Keser[7], Alex Morgounov[8]

[1]ICARDA, Syria, [2]ICARDA, Syria, [3]ICARDA, Syria, [4]ICARDA, Syria, [5]ICARDA, Syria, [6]ICARDA, Syria, [7]ICARDA, Syria, [8]CIMMYT, Turkey

Sunn pest, Eurygaster integriceps Puton, is the most important insect pest of wheat in West and Central Asia. Host plant resistance is the most economical and practical means for controlling insects. The Focused Identification of Germplasm Strategy (FIGS) enables large genebank collections to be "mined" for specific traits such as insect pest resistance. FIGS is based on the paradigm of co-evolution of, and interaction between, host and pest. It analyzes the agro-climatic characteristics of sites from which plant germplasm was originally collected, to make predictions of best-bet accessions that are most likely to contain the trait of interest. FIGS was used to identify trait-specific best-bet subsets from a total of 16,000 geo-referenced accessions conserved in the genebanks of the International Center for Agricultural Research in the Dry Areas, the Vavilov Institute and the Australian Winter Cereals Collection. The selected material was field screened in cages under artificial infestation in Syria for resistance to Sunn pest at the vegetative stage. Out of a total of 1000 wheat accessions tested, 10 durum wheat and nine bread wheat lines showed a very good level of resistance at the vegetative stage. The results also showed the effectiveness of the FIGS approach in identifying genotypes with valuable traits. FIGS has the potential to reduce the resources required to exploit genetic resource collections. Crosses with the identified sources of resistance have been made to develop resistant germplasm to Sunn pest and also mapping populations to identify chromosomal region(s) and molecular markers linked to the resistance.

The shift towards controlling secondary pests on Bt-cotton and the implication thereof for Integrated pest management on Bt-cotton.

Annette Bennett[1], Neethling du Toit[2], Tanya Joffe[3]

[1]Malaria Entomology Research Unit, School of Pathology, Faculty of Health Sciences, WITS, South Africa, [2]Agri-Biotech Research Consultancies cc., South Africa, [3]Syngenta (Pty) Ltd, Midrand, South Africa, South Africa

With the introduction of new technologies on cotton in South Africa, such as single gene traits and double gene traits, which express not only insect tolerance but also herbicde resistance, the emphasis of chemical control on Bt-cotton varieties has shifted towards controlling the secondary pest complex on cotton. The bollworm complex is controlled by the inherent characteristics of the cotton varieties, i.e. the Bt-endotoxin, which is expressed in the plants, and bollworm numbers are kept under economically damaging levels throughout the season. Fewer chemicals aimed at bollworm control are subsequently sprayed, and the absence of any possible 'secondary effect' that these insecticides would have had on non-target pests, has placed the aim of pest control on secondary insects such as aphids, leafhoppers and stainers, while taking predatory numbers into account. Secondary pest numbers on Bt-cotton are presented, and the pegboard, or Cotton Calculus as a scouting tool is discussed, as part of an Integrated Pest Management approach on Bt-cotton.

Reiterating the positive influence of surrounding vegetation in insect resistance management of Bt corn in a tropical country like the Philippines

Merdelyn Caasi Lit

University of the Philippines Los Bano, Philippines

Ten years after its introduction in the Philippines, Bt corn planting had immensely increased around the Philippines. The new growth points in the last five years were in Central Luzon and in many parts of Mindanao (BPI, 2011). The hectarage and volume of production has significantly increased (BAS 2010, James 2010) coupled with the establishment of feed mills in those areas. Although climate change events are a threat, corn production is still constrained by pests and diseases. Bt corn has effectively regulated the most serious pest of corn, the Asian corn borer (ACB), Ostrinia furnacalis (Guenee). After a decade, there has been no report of development of ACB resistance in the original YieldGard hybrid that was introduced and in other Bt hybrids that followed. This paper reiterates the role of surrounding vegetation especially the alternate hosts (weeds and other economic crops) of ACB in insect resistance management of the original Bt hybrids and the second generation stacked Bt corn products. It discusses the role of other natural mortality factors that will create the variability in the ACB populations that will delay the development of resistance. This also takes into consideration the unique tropical setting of the country, the natural temporal refuge that can be harness if given due importance and the knowledge that most corn farmers only have at most a hectare to till..

Terrestrial arthropod biodiversity in Bt corn fields: Assessing the impacts of Bt corn on non-target groups in the Philippines with special focus on uncommon or environmental indicator species

Ireneo L. Lit[1], Merdelyn Caasi Lit[2], Kristine P. Abenis[3], Veverle Da. San Juan[4], Nolan Antoni Q. Manalo[5], Orlando L. Eusebio[6], Ariel R. Larona[7], Aimee Lynn A. Barrion-Dupo[8], Leonila A. Corpuz-Raros[9]

[1]University of the Philippines Los Bano, Philippines, [2]University of the Philippines Los Bano, Philippines, [3]University of the Philippines Los Bano, [4]University of the Philippines Los Bano, Philippines, [5]University of the Philippines Los Bano, Philippines, [6]University of the Philippines Los Bano, Philippines, [7]University of the Philippines Los Bano, Philippines, [8]University of the Philippines Los Bano, [9]University of the Philippines Los Bano, Philippines

The Philippines, being the first one to introduce Bt corn in Southeast Asia has been reaping the benefits of this technology. Hectarage and volume of corn production has increased along with farmers' income (BAS 2010, James 2010). Evidences from a series of fieldwork have shown that planting Bt corn has encouraged a wide range of arthropods in the corn field thus increasing diversity. This increase is probably a consequence of great reduction in pesticide use. Reduced pesticide use, or none at all, in turn, helps protect the environment and promotes better human health. This paper documents the arthropods associated with corn especially those ones not yet reported to occur in the Philippines. Previous studies documented mostly the pest species (e.g. Gabriel (1997). There was no record of other species that belong to other functional guilds or those species that serve as biological indicators or uncommon species. Relatively recent papers recorded parasitoids and predators associated with corn pests as part of the search for alternative control measures against major insect pests of corn in the past few decades. As farmers do not spray their corn fields anymore or if ever, very seldom, the resulting change in the environment, i.e. reduced toxic chemical concentrations, encourages diversity of arthropods in corn agroecosystems or communities.

Effectiveness of transgenic bt cotton on the non-target sucking insect pest's community

Muhammad Arshad[1], Anjum Suhail[2], Muhammad Dildar Gogi[3], Muhammad Hamid Bashir[4], Zain ul Abdin[5], Muhammad Ahsan Khan[6]

[1]University of Agriculture Faisalabad, Pakistan, Pakistan, [2]University of Agriculture Faisalabad, Pakistan, Pakistan, [3]University of Agriculture Faisalabad, Pakistan, Pakistan, [4]University of Agriculture Faisalabad, Pakistan, Pakistan, [5]University of Agriculture Faisalabad, Pakistan, Pakistan, [6]University of Agriculture Faisalabad, Pakistan, Pakistan

The transgenic Bt cotton can effectively control specific lepidopterous species but there is lack of resistance against non-target sucking insect pest's community. Among the non-target, sucking insect pests, cotton whitefly, jassid, thrips aphid and cotton mealy bug are the most important in Pakistan. These are very destructive pests during seedling and vegetative phase of cotton. A little attention is given on the non-target, sucking insect pest's community in Bt cotton as most of the studies focus on major target lepidopterous pests. So, the sucking pests have become a more significant part of pest complex in Bt cotton throughout the world. It is therefore, the study was planned to measure the effectiveness of transgenic Bt cotton against sucking insect pests community under field conditions. The transgenic Bt-cotton line, "IR-FH-901" was compared with its parent non-transgenic, conventional cotton cultivar, "FH-901" under sprayed and unsprayed conditions. The experimental fields were laid out in a Randomized Complete Block Design (RCBD) consisting of four treatments each with four replications. The results revealed no significant differences in population density of these non-target sucking pests between Bt and non-Bt cotton. Regarding sucking pests management no significant differences were found in insecticide applications between Bt and non-Bt cotton. So, for the long term implementation of Bt cotton as a component of IPM, it is important that such varieties should be transformed with Bacillus thuringiensis (Bt) toxin genes, which also have some resistance traits against these non-target sucking insect pests to reduce the number of insecticide applications.

Effectiveness of the Bph3 resistance gene against planthoppers in the Philippines

Ainara Penalver
International Rice Research Institute - Lancaster University, Philippines

Since 2002, frequent and severe outbreaks of the brown planthopper (Nilaparvata lugens)(BPH) have occurred on rice throughout Asia. One theory suggests that these new outbreaks have resulted from a general increase in susceptibility of rice varieties throughout the region. Evidence indicates that resistance in rice with the Bph3 gene has remained relatively stable. We examined rice varieties with Bph3 in the Philippines for their resistance against BPH. We also investigated factors that may contribute to a decline in resistance of these varieties during normal plant growth, and the effects of planthopper adaptation to resistant varieties. Rice varieties deemed to contain the Bph3 gene were variably resistant to BPH in the Philippines. Some varieties (i.e., IR60 and IR62) were highly resistant to the hoppers as determined from several bioassays. Resistance in IR62 was stable throughout plant growth increasing in effectiveness as plants aged. In one bioassay, resistance declined under high nitrogen levels, but these effects were inconsistent. Virulent BPH (that had adapted to IR62) were capable of feeding on all varieties with the Bph3 and bph4 genes. We are continuing to examine the effects of several classes of insecticide on resistance bestowed through Bph3. Evidence so far suggests that increased susceptibility in the field could result from both adaptation by hoppers to long-term deployed resistance genes and poor management of varieties with currently effective genes.

Evaluation of fumigant toxicity of essential oils from three medicinal plants against *Callosobruchus maculatus* adults (Coleoptera: Bruchidae)

Gholamhossein Moravvej[1], Arezoo Heydarzade[2], Zahra Golestani Kalat[3]

[1]Ferdowsi University of Mashhad, Iran, [2]Ferdowsi University of Mashhad, Iran, [3]Ferdowsi University of Mashhad, Iran

Fumigant toxicity of essential oils from Satureja hortensis (Lamiaceae), Teucrium polium (Lamiaceae) and Foeniculum vulgare (Apiaceae) were evaluated against adults of cowpea seed beetle, Callosobruchus maculatus exposed for 24h. Essential oils were obtained by hydro-distillation using a Clevenger-type apparatus. Experiments were conducted at 28±2°C and 60±5% R.H. in dark condition. Gas chromatography coupled with mass spectrometry was used to identify the main components of the essential oils. The principal constituents of F. vulgare oil were E-anethole (60.61%) and fenchone (12.14%) and those of S. hortensis oil were carvacrol methyl ether (50.13%) and thymol (26.77%). Teucrium polium oil mainly consisted of piperitenon oxide (21.72%), α-pinene (11.33%) and carvon (11.29%). All essential oils showed high fumigant activity against C. maculatus adults. The results indicated that mortality of 1-day-old adults increased with oil concentration. Males were more susceptible to oils than females. The essential oil of F. vulgare proved to be the most potent toxicant with the LC50 values of 21.43 and 29.6 µlL-1 air against males and females, respectively. The LC50 values of S. hortensis oil were 74.17 and 156.73 µlL-1 air and the counterpart values of T. polium oil were 60.1 and 80.93 µlL-1 air against males and females, respectively. The results demonstrated that the essential oils of these plants can be considered as the potential protectants against cowpea seed beetle.

Monitoring of bifenazate and etoxazole resistance in two-spotted spider mite, *Tetranychus urticae*

Sangeun Park[1], Hyun-Na Koo[2], Gil-Hah Kim[3]

[1]Chungbuk National University, Republic of Korea, [2]Chungbuk National University, Republic of Korea, [3]Chungbuk National University, Republic of Korea

The two-spotted spider mite, Tetranychus urticae Koch (Acari: Tetranychidae), is one of the most important pest species devastating many horticultural and ornamental crops and fruit trees. Difficulty in managing this mite is largely attributed to its ability to develop resistance to many important acaricides. Two strains were collected from the rose greenhouse in Chillgok and Buyeo in December 2000, respectively. These population has been selected for eleven years with bifenazate or etoxazole (over 500 times), and increased 856- and over 5,000,000-folds in resistance as compared with susceptible strain, respectively. Bifenazate- and etoxazole-resistant strains were both shown to be maternally inherited. By analyzing the mitochondrial cytochrome b (cytb) sequence, G126S point mutation was detected in bifenazate-resistant strain. Two molecular detection methods, quantitative sequencing (QS) and PCR amplification of specific alleles (PASA) were well detected specific G126S point mutation. However, point mutation of cytochrome c oxidase subunit I (COX1), COX2, COX3, cytb, NADH dehydrogenase subunit 1 (ND1), ND2, ND3, ND4, ND5, and ND6 gene was not detected in etoxazole-resistant strains. Thus, point mutation of etoxazole should be studied continually and G126S point mutation in the mitochondrial cytb is available molecular detection marker for selection of bifenazate resistance

DuPont™ Cyazypyr™ insect control (DPX-HGW86, cyantraniliprole,): Product attributes that Influence effective pest control and crop improvement

Isaac Billy Annan

DuPont Crop Protection, Stine-Haskell Research Center, Newark DE 19714-0030. USA, U.S.A.

DuPont™ Cyazypyr™ (cyantraniliprole, DPX-HGW86), is the second molecule of the anthranilic diamide chemistry (IRAC Group 28 insecticides) to be commercialized, but the first active ingredient that shows excellent efficacy on a cross-spectrum of important pests of agronomic crops. Pests that are well controlled include whiteflies, psyllids, aphids, planthoppers, leafhoppers, Lepidoptera, weevils, beetles, sawflies, fruit flies and leafminers. But the product exhibits all these unique features, while still conserving beneficial arthropods. Cyazypyr™ is effective on multiple life stages of pests, and thus ensures effective control of damaging pest populations. Cyazypyr™ is selectively active on the insect ryanodine receptor site, causing rapid impairment of muscle function which in turn results in rapid cessation of feeding, and impairment of locomotion, mating and other muscle-controlled insect activities. The rapid feeding cessation ensures that plants are protected from the direct feeding damage by pests, and also in reduced incidence of pest-vectored plant pathogens that would adversely impact growth and yield performance of crop plants. Key physico-chemical properties such as good solubility in water and ideal Log Kow confer excellent translaminar and xylem translocation properties on products powered by DuPont Cyazypyr™. Overall, the novel mode of action, unique cross-spectrum pest control feature, outstanding plant protection, preservation of beneficial arthropods, excellent translaminar and systemic movement, lack of cross resistance with other known existing products, among other product attributes, make Cyazypyr™ an ideal product to complement IPM and IRM programs in plant protection and crop production systems.

DuPont™ Benevia™ (DPX-HGW86, Cyazypyr™, cyantraniliprole): Control of *Idioscopus clypealis* on mango in the Philippines

Oscar Degracia Edralin[1], Rodelio Flores Macatula[2], Reginald Aquino Quilloy[3], Rachel P. Lomibao[4], Isaac Billy Annan[5]

[1]DuPont Far East, Inc., Philippines Field Research Station, Calauan, Laguna, Philippine, Philippines, [2]DuPont Far East, Inc., Philippines Field Research Station, Calauan, Laguna, PHILIPPINES, Philippines, [3]DuPont Far East, Inc., Philippines Field Research Station, Calauan, Laguna, Philippines, Philippines, [4]DuPont Far East, Inc., Carmelray Industrial Park I, Canlubang, Laguna 4028 Philippines, Philippines, [5]DuPont Crop Protection, Stine-Haskell Research Center, Newark DE 19714-0030. USA, U.S.A.

Benevia™ (DuPont™ Cyazypyr™ 100 OD) is the third diamide compound (IRAC Group 28 insecticides) to be commercialized. Benevia™ and other products powered by DuPont™ Cyazypyr™ show a cross spectrum activity on key sucking, chewing and rasping arthropod pests on a broad range of crop groups, including large fruits, small fruits and other tree crops, vegetables. Mango, Mangifera indica L., is a very important crop in the Philippines, and is considered to be the national fruit. The mango hopper, Idioscopus clypealis Lethierry (Hemiptera: Cicadellidae), is considered as the most serious pest of mango in the Philippines. It causes damage to developing panicles, abortion of flowers, dropping of fruits and ultimately severe reductions in mango yields. Other important pests include the oriental fruit fly. Benevia™ shows excellent controls of those two important pest groups, among others, and also provides outstanding plant protection. Benevia™ has no adverse effect on the predator and parasitoid natural enemies of pests, and the product also controls pest populations that are resistant to other insecticide products. Therefore, Benevia™ has an excellent fit in integrated pest management (IPM) and insecticide resistance management (IRM) programs. Data on the control of Idioscopus clypealis and of crop performance will be discussed.

Sulfoxaflor: A Novel insecticide for management of brown planthopper on rice

Jim Xinpei Huang[1], Jim Dripps[2], Samangwong Somsak[3], Lakshmipathi Srigiriraju[4], Lap Nguyen[5], Aya Kobayashi[6], Peng Wang[7], Jee Hwan Yi[8], Alisa Yu[9], John Breen[10], Jamey Thomas[11], Jon Babcock[12], Ikou Shiraishi[13]

[1]Dow AgroSciences, U.S.A., [2]Dow AgroSciences, U.S.A., [3]Dow AgroSciences, U.S.A., [4]Dow AgroSciences, U.S.A., [5]Dow AgroSciences, U.S.A., [6]Dow AgroSciences, U.S.A., [7]Dow AgroSciences, U.S.A., [8]Dow AgroSciences, U.S.A., [9]Dow AgroSciences, U.S.A., [10]Dow AgroSciences, U.S.A., [11]Dow AgroSciences, U.S.A., [12]Dow AgroSciences, U.S.A., [13]Dow AgroSciences, U.S.A.

Sulfoxaflor, discovered by and proprietary to Dow AgroSciences, is a member of a new chemical class of insecticides, the sulfoximines. Sulfoxaflor is being developed for use in all major crop groups globally, including cotton, soybeans, cereals, rice, citrus, leafy and fruiting vegetables, cole crops, grapes, apples, and many other crops. Sulfoxaflor controls economically important and difficult-to-control sap-feeding insect pests such as tarnished plant bugs, many species of aphids, jassids, whiteflies, planthoppers, and certain scales. A multi-year, multi-location field trial program was conducted in countries such as China, India, Japan, Thailand, and Vietnam, and results showed that sulfoxaflor had an excellent fit into the rice market for management of brown planthopper (Nilaparvata lugens), a key pest in all major rice-growing regions. Sulfoxaflor provided commercial levels of efficacy against this pest at low use rates (50-100 gai/ha). It was also fast acting (knockdown at 1-2 days after application), with extended residual control of up to 21 days after application. Due to its novel chemistry, distinct mode of action and lack of cross-resistance with a variety of other insecticides, sulfoxaflor will be a valuable rotational partner with other chemistries, play a key role in insect resistance management, and serve as an effective pest control tool for rice growers.

Spinetoram, a new spinosyn insecticide for managing key insect pests of rice

Jim Xinpei Huang[1], Jim Dripps[2], Samanwong Somsak[3], Lakshmipathi Srigiriraju[4], Peng Wang[5], Jee Hwan Yi[6], Alisa Yu[7]
[1]Dow AgroSciences, U.S.A., [2]Dow AgroSciences, U.S.A., [3]Dow AgroSciences, U.S.A., [4]Dow AgroSciences, U.S.A., [5]Dow AgroSciences, U.S.A., [6]Dow AgroSciences, U.S.A., [7]Dow AgroSciences, U.S.A.

Spinetoram is a new active ingredient in the spinosyn class of chemistry and is created via two chemical modifications to naturally-occurring spinosyns. These modifications increase insecticidal activity and photostability. Spinetoram was registered under the US EPA Reduced Risk Pesticide Initiative and received a US Presidential Green Chemistry Challenge Award in 2008. Spinetoram has been registered on rice in many countries for management of certain insect pests. The efficacy of spinetoram against leafroller (Cnaphalocrocis medinalis) and stem borers (Chilo suppressalis, Tryporyza incertulas) and other insect pests on rice has been demonstrated in field trials and under conditions of commercial use around the world. At 18-27 gai/ha spinetoram provided larval control and leaf protection, with a good knockdown at 1 day after application and residual activity of up to 14 days. In addition to high activity on young (1st-2nd instar) larvae of rice leafroller, spinetoram was also effective against large (3rd-5th instar) larvae of this pest. For rice stem borers, spinetoram at 30-36 gai/ha provided control in both early (dead heart) and late (white ear) stages of rice crop development. Spinetoram has the same unique mode of action as spinosad (IRAC Group 5), has low toxicity to mammals and other non-target organisms, and does not accumulate in the environment because it is rapidly degraded in soil and natural surface waters. It has minimal effects on most beneficial arthropods and has an excellent fit in rice IPM programs. Spinetoram is becoming a powerful new tool for integrated management of lepidopteran pests in rice.

Response to Insecticides of spotted wing drosophila from British Columbia, Canada

Michael Smirle[1], Cheryl Zurowski[2], Brittany Derrick[3], Joan Cossentine[4]

[1]Agriculture & Agri-Food Canada, Canada, [2]Agriculture & Agri-Food Canada, Canada, [3]Agriculture & Agri-Food Canada, Canada, [4]Agriculture & Agri-Food Canada, Canada

Spotted wing drosophila (SWD), Drosophila suzukii Matsumura, was first discovered in Canada in 2009 in the province of British Columbia, and has been identified as a pest with serious potential economic consequences. Studies were initiated to identify insecticides with acceptable efficacy and environmental profiles, and to generate data required to bring these materials to registration. Twelve materials representing diverse chemical classes and modes of action have currently been tested on male and female flies using a contact bioassay. 4-5 doses of insecticide were dissolved in acetone, introduced into glass vials, and the solvent evaporated while the vials were rotated to produce an even film on the glass surface. Mortality was assessed after 24 hours. Some materials had acceptable efficacy: malathion (organophosphate), Entrust (spinosad) and Delegate (spinetoram) (both spinosyn-based products), as well as the synthetic pyrethroids Ripcord (ctpermethrin) and Matador (lambda-cyhalothrin). Other materials had intermediate activity: Concept (imidacloprid + deltamethrin), tolfenpyrad, and Pyganic (pyrethrum). Additional materials were tested but did not show activity towards SWD. Significant differences in tolerance between male and female flies were observed for spinosad and spinetoram (spinosyn-based materials) and also for Pyganic, although wide confidence intervals in the Pyganic data make these results difficult to interpret. It was also observed that younger flies (24-48 hours as adults) were more tolerant to most materials than older flies 5 days of age or older. The requirement to use flies of consistent age as bioassay subjects is evident.

Determination of acute toxicity (LD50s) of metaflumizone to *Helicoverpa armigera* ,Spodoptera exigua (Lepidoptera: Noctuidae) and *Leptinotarsa decemlineata* (Coleoptera: Chrysomelidae) in lab bioassays

Philippos M. Ioannidis[1], Zois Zartaloudis[2], Costas Bozoglou[3]

[1]Hellenic Sugar Industry S.A., Greece, [2]NAGREF, Greece, [3]BASF Hellas, Sindos Industrial area 57022 Thessaloniki, Greece

The pests Helicoverpa armiqera in cotton, Spodoptera exiqua attacking many crops and Leptinotarsa decemlineata in potatoes have been developed resistance to different insecticides throughout the world and also in Greece, the determination of the LD50s for a new coming insecticide in the market is very important and necessary for establishment Base-line data for comparison of effectiveness among different compounds, comparison between different populations and early determination of possible beginning of resistance. The commercial formulation of the insecticide Alverde 24 sc (metaflumizone) was used in the Bioassays. Larvae L2 were exposed to different doses using the leaf-dip method. Cotton leaves for Helicoverpa armigera, sugar beet leaves for Spodoptera exigua and potato leaves for Leptinotarsa decemlineata (approximately the same size) were dipped into the test solution for 10seconds then allow to dry before put in to the dishes. Data were analyzed by probit analysis (finney). Assessment of mortality was estimated in 24h, 48h and 72h. LD50s for Helicoverpa armigera were correspondently 150, 94, 17.95 ppm of active ingredient, for Spodoptera exigua were 389,103, 23.24 and for Colorado potato beetle were 67.54, 14.73, 3.23. The maximum mortality was obtained in 72h which is the appropriate time for estimated the LD50s and for Colorado potato beetle for getting fast results the 48h is appropriate. The insects used in the bioassays were already resistant to some synthetic pyrethtoids. The toxicological profile, the low mammalian toxicity, the lack of cross resistance of metaflumizone to other insecticides making it ideal for use in integrated pest management systems.

Keywords:*Resistance, Metaflumizone, Spodoptera exigua, Helicoverpa armigera, Leptinotarsa decemlineata*

DuPont™ Cyazypyr™ (cyantraniliprole, DPX-HGW86), is the second anthranilic diamide compound (IRAC Group 28 insecticides) to be commercialized. It has unique cross-spectrum efficacy on both sucking and chewing pests of rice and other agronomic crops throughout the world. Cyazypyr™ has excellent activity on a cross-spectrum of important crop pests, including key pests of bulb vegetable crops like onions, shallot and leek. The rapid cessation of pest feeding by Cyazypyr™ produces outstanding protection of onion from pest damage. Several field studies in the Asia-Pacific region indicate that among the key pests that are controlled by the products powered by DuPont™ Cyazypyr™ include:Delia antiqua(onion maggot), Thrips tabaci(onion thrips), Frankliniella occidentalis(western flower thrips), Liriomyza spp.(leafminers) and Laphygma exigua(beet armyworm). While Cyazypyr™ products provide excellent control of pests, they do not show any adverse impact on predators, parasitoides and beneficial arthropods in general. Also, Cyazypyr™ products are able to control pest populations that are resistant to other insecticides with different modes of action. Therefore, Cyazypyr™ products are very important in intergrated pest management (IPM) and insecticide resistance management (IRM) programs. Examples of field data will be presented.

Effect of the extracts of *Embelia ribes* Burm. f. (Myrsinaceae) leaf on a nontarget organism, Lynx spiders: *Oxyopes lineatipes* C.L. Koch (Araneae: Oxyopidae)

Ondrej Kosulic[1], Cholakan Nuansuwon[2], Wannisa Muangmanee[3], Titiya Pung[4], Patchanee Vichitbandha[5]

[1]Agronomical Faculty, Mendel University in Brno, Zemedelska 1, 613 00 Brno, Czech Republic, [2]Faculty of Science, Prince of Songkhla University, Thailand, [3]Faculty of Science, Prince of Songkla University, Thailand, [4]Faculty of Liberal Arts and Science, Kasetsart University, Kamphaeng Saen Campus, Nakhon Pathom, Thailand, [5]Faculty of Liberal Arts and Science, Kasetsart University, Kamphaeng Saen Campus, Nakhon Pathom, Thailand

Spider is one of common fauna in agroecosystem and plays an important role as the generalist pest control agent. In order to investigate the potential use of the new natural product in pest control, Oxyopes lineatipes C.L. Koch was used as nontarget organisms, since it was the dominant species found in physic nut plantation. The plant extracts of Embelia ribes Burm. f. (Myrsinaceae) leaf by fixed-bed contacting method with hexane was evaluated together with two commercial pesticides; amidine (a synthetic acaricide) and azadirachtin (another natural product). The extraction was dissolved into four concentration levels (0.616% w/v; 1.907% w/v; 2.748% w/v and 3.5 % w/v), with 10% ethanol. Commercial pesticides, amidine and azadirachtin, were dissolved in water into 0.4 % w/v and 0.0025 % w/v, respectively. Water and 10% ethanol were served as control solution. Within 2 hours in laboratory studies, 83% of O. lineatipes were poisoned by 50-$\mu\ell$ sprayed of Amidine, but neither by 0.616% E. ribes plant extracts, azadirachtin nor water. However, the higher concentrations of E. ribes plant extract resulted in higher mortality of O. lineatipes than 50% of total trials but within the longer period of time; 116 hours, 103 hours and 10 hours, respectively. All of O. lineatipes died after contacted with amidine for 21 hours, but some spiders still were alive in all other treatments at the end of an experiment (116 hours). The LC50 of this plant extracts were 1.38 and 1.27 % w/v at 24 and 84 hours, respectively.

Keywords:*Lynx spiders, plant extracts, Embelia ribes, Amidine, Azadirachtin, nontarget, LC50*

Lethal effects of four insecticides on different developmental stages of *Chrysoperla carnea* Stephens (Neuroptera: Chrysopidae) in laboratory conditions.

Gholamhossein Moravvej[1], Javad Karimi[2], Ali JUYANDE[3], Aida Ayubi[4]

[1]Ferdowsi University of Mashhad, Iran, [2]Ferdowsi University of Mashhad, Iran, [3]Research Center of Khorasan Razavi Province, Mashhad, Iran, [4]Ferdowsi University of Mashhad, Iran

The common green lacewing Chrysoperla carnea Stephens is a general biocontrol agent of several insect pests in greenhouses. The lethal effects of four compounds including imidacloprid, lufenuron, thiametoxam and thiodicarb on eggs, 1st instar larvae and adults of C. carnea were studied in laboratory conditions (25±2 ºC, 60±10% RH and 10-h photo phase). Dipping bioassay tests were used for eggs and residual contact method for larvae and adults. Positive relationships were detected between the concentrations of insecticides and mortality rates of various stages. However, there were considerable variations in toxicity of insecticides. Thiodicarb had no effect on eggs, whereas thiametoxam with the LC50 value of 1.90 µg ai L-1 showed the highest ovicidal activity. On larvae, thiametoxam was the most toxicant (LC50= 0.55 µg ai L-1) and lufenuron proved to be the least (LC50 = 44.02 µg ai L-1). The results of adult experiments indicated that males were more susceptible than females to all insecticides except Lufenuron to which no lethal effect was observed. Thiametoxam proved to be the most potent toxicant against males (LC50= 8.83 µg ai L-1) and females (LC50= 73.05 µg ai L-1). The use of thiametoxam should be carefully evaluated if employed in combination with C. carnea in IPM programs. Imidacloprid and thiodicarb are moderately harmless and lufenuron considered being safe for C. carnea.

Keywords:*Chrysoperla carnea, imidacloprid, lufenuron, thiametoxam, thiodicarb*

Investigations on the effects of two different plant extracts on the green peace aphide [(*Myzus persicae* Sulzer) (Hom.: Aphididae)]

Pervin Erdogan

Ministry of Agriculture, Plant Protection Central Research Institute, Turkey

Green peach aphid [(Myzus persicae Sulzer) (Hom.: Aphididae)] is a very important pest worldwide, causing serious damage to vegetables, flowers and fruit crops. Green peach aphid is also an economic pest in Turkey. The use of plant extracts as an alternative pesticides for control of insects is becoming important. A great deal of research has been carried out in this area in recent years. The efficacy of pesticides extracted from two different plants such as Allium sativum L. (Amaryllidaceae) and Capsicum annum L. (Solanaceae) were tested as alternative insecticides. The effects of extracts with ethanol obtained from two different plants on Green peach aphid were investigated. Bioassays to were tested by two different methods determine the effects of varying concentrations. Experiments were performed using 3 cm diameter leaf disk from unsparayed the radish plants [Raphanus sativus L. (Brassicaceae)]. Experiments were carried out using (3cm diameter) leaf disks of R. sativus. The effects of four concentrations of extract %1, 3, 6, 12 were studied. All of experiments were repeated 10 times. As a result of the investigation, in leaf dipping method; the extract of C. annum %12 concentration showed the highest mortality in nymph and adult stages. There was a not significant difference on the mortality between leaf dipping and direct leaf spraying method when compared. The research undertaken in the laboratory at the Ankara Plant Protection Central Research Institute in 2010 tested the insecticidal effect of two plants extracts against Green peach aphid.

Semi-field and field evaluations of spatial repellents for mosquitoes

Daniel Lee Kline
USDA-ARS, CMAVE, U.S.A.

A spatial repellent is a chemical compound that in the vapor phase can produce repellency at a distance, significantly reducing the number of target species in a defined area over a designated period of time. Several compound classes have been reported to produce spatial repellency of Aedes aegypti, including essential oils, such as citronellal and geraniol, pyrethrums and synthetic pyrethroids. Several commercial products have been produced utilizing these compounds. Although many of these commercial products appear to show promise, they have not been adequately evaluated in peer-reviewed studies. The studies reported in this presentation were conducted in attempt to help fill that knowledge gap. Protocols were developed to evaluate these commercial products and other candidate compounds in laboratory olfactometer, semi-field and field studies against laboratory reared and/or natural populations of mosquitoes. It was determined that these compounds have both mortality and repellency properties. `Olfactometer studies emphasized screening candidate essential oil compounds; semi-field and field studies emphasized evaluations of an increasing array of commercial products, which contain active ingredients such as metofluthrin and allethrin.

Immunochemical techniques: Effective tool for pesticide residue detection

Prabha Sharma[1], Devinder Kaur Kocher[2]

[1]Punjab Agricultural University, India, [2]Punjab Agricultural University, India

Chlorpyrifos, being successfully detected by GC, LC and HPLC with great sensitivity and reliability. However, these are typically burdened with time-consuming sample preparation steps, skilled analysts, low detection level, high expenditure and false positives. Hence, immunochemical techniques supplement traditional analytical methods in an ideal way because they are extremely fast, sensitive, simple and inexpensive. The most important types presently used for environmental analysis are immunoassays, immunosensors, immunochromatography, and immunolabeling. The progress of development of new immunoassays and related immunotechnologies requires the availability of antibodies with the desired affinities. A critical step in the production of monoclonal antibodies is the development of efficient screening procedures to identify suitable hybridoma lines. The usefulness of immunomagnetic cell separation for the screening of hybridomas is based on the expression of surface receptors resembling the secreted antibodies on the membrane surface of hybridoma cells. Producers are tagged by the target molecule covalently linked to magnetic beads and subsequently removed by permanent magnet. Immunomagnetic beads offer an alternative to conventional screening with immunoassays as it can solve the problems like much time-consumption, escaping detection or loosing valuable cells. This technique is based on tagging, surface receptors of hybridoma cells with binding properties of the secreted antibodies by magnetic beads, which are coated with hapten conjugates. In spite of the considerable progress in hybridoma technology, antibody development has entered an entirely new domain because of the potential of recombinant antibodies. This technology will eventually allow faster production of antibodies with stepwise abandonment of animal experiments.

Studies on the evaluation of new chemistry insecticide (Spinosad) and some plant extracts against *Rhyzopertha dominica* (Fab.) (Bostrichidae: Coleoptera)

Mansoor Ul Hasan[1], Muhammad Sagheer[2], Qurban Ali[3]

[1]University of Agriculture Faisalabad, Pakistan, Pakistan, [2]University of Agriculture Faisalabad, Pakistan, Pakistan, [3]University of Agriculture Faisalabad, Pakistan, Pakistan

The efficacy of plant products onion and garlic, and new chemistry insecticude spinosad against Rhyzopertha dominica was studied under the laboratory condition of 32±2C and 70±5% R.H. following completely randomized design. Experiment was carried out on direct mortality. Expermental jars were washed cleaned and dried carefully to avoid any possibility of pathogenic infestation. Three concentrations of spinosad, onion and garlic such as 0.50, 0.75 and 1.00% were mixed in 100gm of fresh sterilized wheat grains for different exposure time (3, 6 and 9 days)and data collected was analyzed statically.The maximum mortality was found in case of spinosad. The remaining survival individuals were taken to assess population build-up. Population build-up data were recorded after 30 and 60 days of liberation of test insects. Observation on mortality basis and population build-up revealed that spinosad was the most effective at all concentrations. The minimum mortality and maximum population buils-up was in case of onion and garlic.

Influence of DuPont™ Benevia™ (Cyazypyr™, cyantraniliprole) on insect pest management and plant protection in leguminous crops in Asia

Lu Ren
Dupont company, China

Benevia™ is a 100 g/L formulated OD product powered by DuPont™ Cyazypyr™ (DPX-HGW86, cyantraniliprole), which is the second anthranilic diamide compound (IRAC Group 28 insecticides) to be developed and commercialized by the DuPont Company. Benevia™ has shown excellent cross spectrum activity on key sucking and chewing insect pests of a broad range of agronomic crops worldwide. Benevia™ controls major pests of legumes crops in the Asia-Pacific region, including cowpeas, mung beans, snap beans, red gram and different types of peas. Among the important pest groups that Benevia™ controls include bean pod borer, vegetable leafminer, pea leafminer, leafhoppers, sweet potato whitefly, cluster caterpillar, cotton leafworm, beet armyworm, aphid and thrips. Benevia™ shows the excellent pest control while still having no adverse impact on key species of arthropod predators and parasitoids that contribute significantly to pest control. Therefore, the product will be a centerpiece of integrated pest management (IPM) programs. Other important attribute is the rapid cessation of pest feeding by Benevia™. This results in the protection of plants from direct damage from pest feeding, and also in reductions of vectoring of plant pathogen by pests. These include cowpea aphid-borne mosaic virus (CabMV), which is transmitted by the cowpea aphid. The benefits are achieved when the product is applied at the early stages of pest infestations before populations reach damaging levels. Benevia™ controls pests that are resistant to other insecticide products, therefore it will become a valuable rotational partner in insecticide resistance management (IRM) programs. Field data will be presented.

Effect of *Ferula assafoetida* L. essential oil on some physiological aspects of the common pistaciae psylla, *Agonoscena pistaciae* under laboratory conditions

Mahshid Sarnevesht[1], Hamzeh Izadi[2], Mohamad Amin Jalali[3]

[1]*Vali-e-Asr University, Iran,* [2]*Vali-e-Asr University, Iran,* [3]*Vali-e-Asr University, Iran*

The common pistachio psylla, Agonoscena pistaciae Burckhardt and Lauterer (Hem: Psyllidae) is known as a key pest of pistachio orchards in Iran. In this study, effect of Ferula assafoetida essential oil (a toxic extract from stinking assa plant) was investigated by measuring glycogen, glucose, lipid and protein contents of the 5th instar nymph of A. pistaciae. The 5th instar nymphs dipped in insecticide for 3s. Treated nymphs allowed to air dry and then located on the pistachio leaves in controlled conditions (27±2 oC, 60±5 RH and 16:8 h L:D). The effect was studied in 24 and 48 hr after treatment. Low molecular weight carbohydrate (glucose) as well as glycogen and lipid contents were measured by methods described by Warburg and Yuval (1996). Protein content of whole body was measured by Lowery method (Lowery et al., 1951). Glycogen content of treated nymphs 24 hr after treatment (19.29 mg/g fresh body weight) and 48 hr after treatment (7.7 mg/g fresh body weight) was significantly lower than control (9.15 and 17.12 mg/g fresh body weight).but no significant difference was observed between protein, lipid and glucose contents of treated nymphs and control (P>0.05). This study revealed that Ferula assafoetida is able to significantly decrease glycogen level of treated 5th instar nymphs in relation to control.

Toxicity of acetamiprid and *Ferula assafoetida* L. essential oil against the common pistachio psylla, *Agonoscena pistaciae* under laboratory conditions

Mahshid Sarnevesht[1], Hamzeh Izadi[2], Mohamad Amin Jalali[3], Hadi Zohdi[4]

[1]Vali-e-Asr University, Iran, [2]Vali-e-Asr University, Iran, [3]Vali-e-Asr University, Iran, [4]Department of Plant Protection, Pistachio Research Center, Kerman, Iran

The common pistachio psylla, Agonoscena pistaciae Burckhardt and Lauterer (Hem.: Psyllidae) is known as a key pest of pistachio orchards in Iran. Chemical control is the common method for the control of this pest, with growing concerns about unwanted impacts of conventional chemicals, investigations on compounds with few environmental side-effects such as plant extracts for pest control receives increasing attention. In this research, susceptibility of the 5th instar nymphs of A. pistaciae to F. assafoetida essential oil, a toxic extract from stinking assa plant, and acetamiprid, a neonicotinoid insecticide, was investigated. Probit analysis of concentration-mortality data conducted to estimate the LC50 values of the test chemicals. The 5th instar nymphs of A. pistaciae dipped in different concentrations of acetamiprid (0.1, 0.15. 0.2, 0.25 and 0.3 g/ml) and F. assafoetida essential oil (3, 4, 5, 6 and 7 ppm) for 2 seconds. Treated nymphs were then allowed to air dry and then located on the pistachio leaves in controlled condition (27± 2°C, 60±5 RH and 16:8 h L:D). The LC50 value was estimated 0.3 g/ml for acetamiprid and 6 ppm for F. assafoetida essential oil after 72 hr. Our results showed that F. assafoetida in comparison with acetamiprid is more effective and toxic against 5th instar nymphs of A. pistaciae.

Gonipterus platensis (Coleoptera: Curculionidae) - Present status and control strategies in colder regions of Portugal

Manuela Branco[1], Ana Raquel Reis[2], Clara Araujo[3], Liliana Vilas Boas[4], Carlos Valente[5]

[1]Instituto Superior de Agronomia. Universidade Tecnica de Lisboa, Portugal, [2]Altri-Florestal Investigacao e Desenvolvimento, Portugal, [3]Altri-Florestal Investigacao e Desenvolvimento, Portugal, [4]Instituto Superior de Agronomia. Universidade Tecnica de Lisboa, Portugal, [5]RAIZ-Instituto de Investigacao da Floresta e Papel, Portugal

The eucalyptus snout weevil Gonipterus scutellatus Gyll. (Coleoptera: Curculionidae), as recently demonstrated, is a complex of cryptic species with different distributions. The eucalyptus snout weevil present in the Iberian Peninsula was further identified as G. platensis, originate from Tasmania. The egg parasitoid Anaphes nitens (Hymenoptera: Mymaridae), originate from South Wales, is the only biological control strategy extensively used worldwide to control this weevil complex. However, the parasitoid fails to effectively control G. platensis in the colder areas of the Iberian Peninsula such as in mountain regions, of the northern and centre of Portugal. Our results on egg parasitism rate, tree defoliation and wood loss following altitudinal gradients show a consistent decreasing of parasitism rates and increase defoliation damage with elevation. Consequently, timber production losses increase steeply with elevation, reaching 90% of wood loss above 700 m. A linear decrease of the parasitism rate with the decrease of the maximum temperature of the winter months is further observed. Therefore, a climatic mismatch between the parasitoid and the weevil is hypothesized. As a result, alternative control strategies are being investigated. We present results on the weevil preference and performance on Eucalyptus species alternative to E. globulus. Further, we discuss the possibility of using natural enemies of G. platensis from Tasmania in a classical biological control program.

Humidity-controlled cold storage of the predatory mite, *Neoseiulus californicus* McGregor (Acari: Phytoseiidae), an important natural enemy of spider mites

Noureldin Abuelfadl Ghazy[1], Takeshi Suzuki[2], Hiroshi Amano[3], Katsumi Ohyama[4]

[1]Chiba University, Japan, [2]Chiba University, Japan, [3]Kyoto University, Japan, [4]Chiba University, Japan

The major obstacles to the successful implementation of biological control are the high cost and poor availability of natural enemies. However, by developing an effective storage method, reduction in the costs and increase in the availability can be achieved. This study aimed at developing such a storage method by controlling humidity and selecting a specific life stage of the predatory mite Neoseiulus californicus, an important natural enemy of spider mites. Larvae, protonymphs, deutonymphs, unmated adult females, and mated adult females of N. californicus were stored at 5°C and relative humidity (RH) of 100% or 80%. The survival period was significantly longer at 100% RH than at 80% RH for all the life stages. Mated adult females exhibited the longest survival. Post-storage reproduction of the stored mated adult females was not affected by storage for up to 30 days. These results showed that mated adult N. californicus females can be stored at 5°C and 100% RH for 30 days without any degradation in post-storage quality.

Dust in apple orchards causes mite outbreaks: Fact or fiction?

Kenneth Llewellyn Pringle[1], Juanita Heunis[2], Marelize de Villiers[3]

[1]University of Stellenbosch, South Africa, [2]University of Stellenbosch, South Africa, [3]Dept. of Conservation Ecology and Entomology, University of Stellenbosch, South Africa

Five apple orchards exposed to varying amounts of dust were used. In each orchard 25 evenly spaced trees were identified as sample trees. One leaf was taken from the periphery and one from the inside of each tree. Adult phytophagous and predatory mites were counted on these leaves, which were placed in a paper bag and transported to the laboratory where all stages were counted microscopically. One leaf was taken from each tree for determining the amount of dust. They were placed individually in paper bags. In the laboratory the dust was washed off and filtered through pre-weighed filter paper, which was dried and re-weighed. The difference in weight before and after filtering represented the weight of dust on the leaves. The area of each leaf was determined, enabling estimation of the amount of dust in terms of mg cm-2. The season with the most dust had the least number of mites and visa versa. Therefore, seasons during which there is a lot of dust do not necessarily result in mite outbreaks. There was no relationship between the amount of dust on leaves from different orchards and mite numbers, suggesting that dusty orchards do not harbour high mite population levels. Of the 15 correlations between the amount of dust on individual trees and the number of mites on these trees, one was highly significant and one was marginally significant. Therefore, trees with a lot of dust do not always harbour more mites than trees with less dust.

Are neonicotinioid insectides which partially replaced organophosphate and carbamate insecticides in U.S. tree fruit safer to native pollinators and biological control?

David Biddinger[1], Neelendra Joshi[2], Jacqueline Robertson[3], Edwin Rajotte[4], Chris Mullin[5], Mace Vaughan[6], James Frazier[7]

[1]Penn State University Fruit Research & Extension Center, U.S.A., [2]Penn State University Fruit Research & Extension Center, U.S.A., [3]LeOra Software, U.S.A., [4]Penn State University, U.S.A., [5]Penn State University, U.S.A., [6]The Xerces Society, U.S.A., [7]Penn State University, U.S.A.

The U.S. Food Quality Protection Act (FQPA) of 1996 has or is in the process of eliminating many of the organophosphate (OP) and carbamate broadspectrum insecticides that eliminated most biological control and many of the native pollinators in the tree fruit orchards of the eastern U.S. Some of the U.S. Environmental Protection Agency classified reduced-risk and OP replacement insecticides that have replaced them are target specfic and are promoting conservation of biological control and possibly native pollinators. Is the widespread use of neonicotinoids in orchards a step forward towards ecologically based IPM? Biodiversity and abundance data from various arthropod taxa, including bees, collected in replicated trials in commercial orchards over 3 years, from sentinel egg masses placed in orchards, bio-assays and field residue analysis from orchard applications will be presented.

Phanerotoma philippinensis, a potential parasitoid for managing legume pod borer, Maruca vitrata

Sopana Yule[1], Srinivasan Ramasamy[2]

[1]AVRDC - The World Vegetable Center East and Southeast Asia, Thailand, [2]AVRDC - The World Vegetable Center, Taiwan

Legume pod borer, Maruca vitrata, is a serious production constraint on yard-long bean, which is grown on approximately 7% of the total vegetable production area in Southeast Asia. M. vitrata can cause up to 80% yield loss on various host plants. Pod borers are difficult to control with chemical pesticides because they burrow into the pods, where they are protected from the pesticide spray. Parasitoids could play a significant role in suppressing borer insects including M. vitrata even when the pests are concealed under or inside plant parts. A systematic effort to identify the most effective parasitoids of M. vitrata in Thailand identified Phanerotoma philippinensis (Braconidae: Hymenoptera) as a major parasitoid. In a monitoring survey conducted during 2011 in Nakhon Pathom, field parasitism up to 21% was recorded. P. philippinensis is an egg-larval parasitoid; the females attack the egg stage, and the adult parasitoid emerges out from the second instar larvae of M. vitrata. A female parasitoid can parasitize about 10-50 eggs in three hours. However, successful emergence of parasitoid adults from the parasitized eggs had an inverse relationship with the host egg density. P. philippinensis females preferred one-day-old eggs of M. vitrata. This parasitoid is amenable to mass-culturing under insectary conditions using M. vitrata eggs as the host. The potential for using P. philippinensis together with different chemical and biopesticides in an integrated pest management strategy will be discussed.

Toxicity of insecticides to *Aphelinus mali*, the parasitoid of woolly apple aphid

David John Rogers[1], Nandita Sharma[2], James Thomas Walker[3]

[1]Plant and Food Research, New Zealand, [2]Plant and Food Research, New Zealand, [3]Plant and Food Research, New Zealand

The parasitoid Aphelinus mali is vital for the successful biological control of woolly apple aphid (WAA; Eriosoma lanigerum) in New Zealand apple orchards. WAA is normally well controlled by A. mali, but there were serious outbreaks in the 2007-08 season, which coincided with the introduction of a new insecticide for codling moth control to satisfy residue restrictions. Bioassays incorporating field application of four insecticides and exposure of A. mali to 0 to 15-day-weathered residues on leaves were used to determine toxicity. Fresh residues of spinetoram, spinosad, thiacloprid and spirotetramat had high, moderate, low and no toxicity respectively as measured by adult mortality. The neonicotinoid thiacloprid also caused paralysis and twitching of the treated insects, resulting in high toxicity as measured by the inability of A. mali to walk. Spinetoram was more persistent than spinosad, resulting in moderate toxicity 7 days after application, whereas spinosad was benign to A. mali at this time. Applications of one eighth field rate of spinetoram had similar residual toxicity to the full rate of spinosad. We postulate that repeated applications of spinetoram were the primary cause of the observed WAA outbreaks, in conjunction with other disruptive insecticides. Spinetoram does not control WAA but is toxic to A. mali leading to widespread severe outbreaks of WAA. Strong dependence on a single biocontrol agent made this IPM system vulnerable to disruption by toxic pesticides. Minimising the use of pesticides toxic to A. mali should benefit the sustainable management of WAA in New Zealand apple orchards.

Biological characteristic and selection of low toxic of pesticides to native predator, *Chrysoperla nipponensis* (Okamoto) (Neuroptera:Chrysopidae) for the control of mealy bugs at pear Orchard.

Eunhye Ham[1], Jun seok Lee[2], Jong kyun Park[3], Young su Lee[4], Mi yeon Jang[5]

[1]Osangkinsect Co., Ltd., Republic of Korea, [2]Osangkinsect Co., Ltd., Republic of Korea, [3]Kyungpook National University, [4]Gyonggi-do Agricultural Research & Extension Services, Republic of Korea, [5]Osangkinsect Co., Ltd., Korea, Republic of

The mealy bug is known as a pests on bark, stem and leave of woody and herbaceous plants, including pear. Mealy bugs are soft-bodied creatures, but they secrete a powdery wax layer over themselves. It makes so difficult to chemical control. The development of new effective native predator against the mealy bugs is of great interest. We found that the lacewing had a potent control efficacy against mealy bugs. The identified DNA sequences indicate that this lacewing species is Chrysoperla nipponensis (Okamoto). C. nipponensis has been commonly used with biological control agents for control of several kinds of pests(aphids, whitefly, thrips, mites and mealy bugs) in agroecosystems, because of its abundance and broad habitat range. The toxicities of 12 commercial pesticides(8 insecticides and 4 fungicides) which have been used in the domestic market were evaluated to C. nipponensis at the recommended concentration. Among 8 insecticides tested, Imidacloprid 10%, Thiamethoxam 10%, Acetamiprid 8%, Methidathion 40%, Acequinocyl 15%, Clothianidin 8% and Deltamethrin 1% showed low toxicity to C. nipponensis. All fungicides tested were very low toxicity. It may be suggested from these results that 7 insecticides and 4 fungicides could be incorporated into the integrated pseudococcidae management system with C. nipponensis on pear orchard.

Insects can enhance the biocontrol potential of pathogens against weeds: A case study on aquatic weed, waterhyacinth in South Africa

Puja Ray[1], Martin P. Hill[2]

[1]Rhodes University, South Africa, [2]Rhodes University, South Africa

While six arthropod agents have been released for biological control of the invasive aquatic macrophyte, waterhyacinth, Eichhornia crassipes Mart. Solms-Laubach (Pontederiaceae) in South Africa, not much research has been done on the plant pathogens of the weed. An approach to enhancing the weed killing effects of pathogens is to facilitate their entry by biologically, physically, or chemically wounding the weeds. Indeed, even ordinarily incompatible pathogens can become infective on otherwise resistant weeds when those plants are injured by various methods, including by insect feeding. Plant pathogens of waterhyacinth have been largely ignored in the country due to their erratic effect. During our recent studies we isolated some promising agents of waterhyacinth, including Alternaria eichhorniae, Acremonium zonatum, Bipolaris hawaiiensis and Fusarium spp. Although most of these isolates appeared severely damaging under controlled conditions their inability to serve as stand-alone replacements for chemical herbicides, has probably deterred their earlier commercialization efforts. Our studies showed potential increase in their pathogenicity in presence of waterhyacinth weevils, Neochetina spp and leaf-sucking bug, Eccritotarsus catarinensis, insect biocontrol agents of waterhyacinth. Thus the presence of six insect agents can be an advantage in enhancing the use of the native pathogens of waterhyacinth as effective biological control agents with their combined applications.

Temperature effects on development of overwintering *Grapholita molesta* (Busck) (Lepidoptera: Tortricidae) from Korean apple orchards

Lalit Prasad Sah[1], Jeong Joon Ahn[2], Chuleui Jung[3]

[1]Andong National University, Republic of Korea, [2]Andong National University, Republic of Korea, [3]Andong National University, Republic of Korea

The oriental fruit moth (OFM), Grapholita molesta (Busck) (Lepidoptera: Tortricidae) is an important economic pest of stone fruits. The objective of the study was to determine the effects of temperature on the development of overwintering G. molesta larvae to adult in the laboratory. Five constant temperatures (15, 20, 25, 30, and 35ºC), with R.H. 75% and a photoperiod of 16L:8Dh were treated The developmental period significantly decreased with increasing temperatures; 53.8, 45.5, 28.5, and 20.7 days at temperatures of 15, 20, 25, and 30°C, respectively. The pupa did not survive at 35°C.The male developed faster than the female especially in larval stage. Linear and nonlinear regression models quantitatively described temperature-dependent development of Grapholita molesta. The developmental threshold temperature for cocooned larvae to adult was 7.3°C with the thermal constant of 490.19 degree days. The female ratio was not different to 0.5. . Morality was lower in 20-25°C treatments but higher in higher or lower temperature. At 35°C, mortality was almost 100%. During this study, we found that substantial proportion of collected overwintering cocoon (25±3.5%) was parasitized. Parameters from this study can be utilized for prediction of spring phenology of G. molesta in apple orchards.

Population management of invasive mealbug, *Phenacoccus solenopsis*(Tinsley) in cotton crop through different modules in Pakistan

Ghulam hussain Abro
Sindh Agriculture University, Pakistan

Phenacoccus solenopsis Tinsley is polyphagous invasive species which has devastated cotton crop in Pakistan in recent years. Studies were carried out on efficiency of parasitoid, Aenasius bambawalei Hayat (Hymenoptera: Encyrtidae) against mealybug, P. solenopsis under field conditions at Center of Agriculture and Bio-sciences, Southeast and West Asia (CABI), Model Farm at Mirpur Khas, Pakistan. Two pest management modules, one practiced by farmer applying insecticides and another biological control module, using natural enemies' field reservoir (NEFR) were tested on cotton crop, 2010. Significantly high pest, parasitoid and predators population development were recorded in NEFR treatment compared with farmer's cotton. The seasonal mean population of P. solenopsis, parasitized pest mummies and predators were 27.40±0.6, and 19.10±0.20 per 10cm twig per plant and 5.46±0.30 per plant, respectively in NEFR cotton. At farmer's field significantly less parasitization of P.solenopsis and less incidences of hyperparasitism by hyperparasitoid, Promuscidea unfasciativentris on A. bambawalei were recorded compared with NEFR. The mean population of A. bambawalei recorded on farmer's cotton was 8.35±1.62, and in NEFR 15.75±1.54 parasitized mealybug mummies per 10cm twig per plant. The population of hyerparasitoid, P. unfasciativentris was 1.59 per twig per plant with 12.38% parasitization of A. bambawalei on farmer's field compared with 3.39 and 17.17 % on NEFR cotton crop. Economic analysis of different pest management strategies showed that the chemical control strategy of farmer gave more than double income compared to NEFR.

Diversity and distribution of natural enemies (predators and parasitoid) of bagworms (Lepidoptera: Psychidae) on various host plants in oil palm plantation

Yusdayati Rashid[1], Che Salmah MD Rawi[2], Abu Hassan Ahmad[3], Noor Hisham Hamid[4]

[1]Felda Agriculture Services , Malaysia, [2]Universiti Sains Malaysia, Malaysia, [3]Universiti Sains Malaysia, Malaysia, [4]Felda Agriculture services, Malaysia

Several species of predators and parasitoids were known to regulate the populations of oil palm (Elaies guineensis: Palmae) bagworms (Psychidae) in FELDA oil palm plantation in Perak, a northern state in Peninsular Malaysia. The abundance and diversity of these natural enemies on three species of host plants; Turnera sp. Cassia cobanensis and Antigonon leptopus was monitored at monthly intervals for 14 months in 2005 ? 2006. Seven hymenopteran and one hemipteran families were identified from 816 individuals collected. Chalcididae was the most dominant family (69.2%) and represented by three species of Brachymeria, B. lasus, B. lugubris and B. carinata. The abundance of natural enemies were significantly different among sampling periods (Kruskal Wallis X2=38.791, $p<0.05$) and host plants (Kruskal Wallis X2= 86.868, $p<0.05$). Most parasitoids including B. carinata and Dolichogenidae metasea preferred C. cobanensis and Turnera sp. over Antigonon leptopus ($z= 2207.5$, $p< 0.05$ and $z=4312$, $p=0.00$ respectively). No significant preference of the parasitoids on C. cobanensis and Turnera sp. was detected ($z= 10571$, $p>0.05$). High abundances of natural enemies were observed on C. cobanensis and Turnera sp due to the presence of stipules on their stems and flowers respectively that produce nectar as a food source for the insects. The plants also provided good shelters for the natural enemies. This study has shown the importance of host plants in oil palm plantation to support high abundance and diversity of natural enemies that would contribute to sustainable control of oil palm insect pests.

Response of cotton mealybug to biological, biochemical and chemical control tactics under semi-field and field conditions

Muhammad Mamoon ur Rashid[1], Masood Khan Khattak[2], Khalid Abdullah[3]

[1]Gomal University, Pakistan, [2]Gomal University, Pakistan, [3]Government of Pakistan, Pakistan

Two trials were carried out under semi-field and field conditions to evaluate the compatibility of native predators, Chrysoperla carnea larvae and adults of Brumus suturalis and the exotic predator Cryptolaemus montrouzieri in combination with neem oil for the control of cotton mealybug, Phenacoccus solenopsis. The assessments were based on mealybug control (scale 0-9) and percent recovery of predators at the end of the experiment showing conservation and colonization capability of the predator to local conditions. Both native predators Chrysoperla carnea and Brumus suturalis showed better control of the mealybug under semi-field and field conditions over the control and were also recovered at the end of the trials. In contrast to these, exotic predator, Cryptolaemus montrouzieri though proved to be the most efficient predator of cotton mealybug, Phenacoccus solenopsis under semi-field conditions but it failed to establish under field conditions and reducing mealybug populations and no recoveries were made of the predator in either of the treatments under field conditions. Maximum reduction in the population of mealybug was noticed in the insecticide treated plants. Our results show that application of neem oil followed by release of C. carnea larvae and B. suturalis adults can be used in swapping to synthetic insecticides for the safer management of mealybug on cotton.

Orientation and feeding responses of *Cotesia plutellae* (Kurdjumov) (Hymenoptera: Braconidae) adults to honey and sucrose

Ashok Kumar Singh[1], Kapinder Kumar[2]

[1]*Delhi University, India,* [2]*Delhi University, India*

Orientation responses of naive, unmated and unfed adults of Cotesia plutellae to honey and sucrose were tested in a T-shaped tunnel. Female wasps showed attraction, antennation and mouth parts extension to honey at a distance in response to its odor. Attraction of females to honey was innate because the wasps derived from sucrose-fed parents showed same level of attraction to honey as those derived from honey-fed parents. Hexane fraction of hexane-extracted honey attracted females, but did not elicit antennation and mouthparts extension. Aqueous fraction of hexane-extracted honey elicited latter two responses but no attraction. Males showed antennation and mouthparts extension responses but no attraction to honey odor. On allowing access to honey, sucrose or sucrose in the midst of honey vapor in feeding chamber, females reached honey directly without preceding random movements. But they took longer to reach sucrose after random movements. Males took longer than females to reach honey and much longer to reach sucrose after prolonged random movements. Sucrose in the midst of honey vapor was found and fed upon in almost same time as honey alone. Although a high percentage of wasps fed on honey, sucrose and sucrose in honey vapor, total duration of feeding of females on honey was longer than that on sucrose but it further extended when sugar was provided in the midst of honey vapor. Males fed on these foods for shorter durations than females. The study of using honey or its fractions in food supplements can be implemented for biological control program.

Biology of *Diaphorina citri* Kuwayama (Hemiptera: Psyllidae) and parasitism by *Psyllaephagus stenopsyllae* (Tachikawa) (Hymenoptera: Encyrtidae) in Baluchestan, Iran

Behnam Motamedinia[1], Qodratollah Sabahi[2]

[1]Iran Research Institute Plant Protection, Iran, [2]Department of Plant Protection, College of Agriculture, University of Tehran, Iran

The Asian citrus psyllid, Diaphorina citri Kuwayama (Hemiptera: Psyllidae), is a major pest of citrus causing damage and vector of citrus greening in south of Iran. In this study, the biological characteristics of each life stage of Diaphorina citri Kuwayama in laboratory conditions (25±1°C, 70±5% R.H. and a photoperiod of 14:10(L: D) hours and parasitism by Psyllaephagus stenopsyllae (Tachikawa) were investigated. The pre-oviposition period of D.citri was 3.9±0.47 days and the incubation period was 3.9±0.47 days. The average number of eggs laid per female was 230.25± 50.7 eggs. The mean of total nymphal period (1st instar to 5th instar) was 14.83±18.7 days. The mean longevity of male and female adults was 21.6±0.5 and 26.6±2.1 days, respectively. Mean parasitism of D.citri by P. stenopsyllae was 7± 6% in 2008.

Persist action of some toxic pesticides on *Trichogramma cacoeciae* Marchal (Hymenoptera: Trichogrammatidae)

Hayder Abdelgader
Agricultural Research Corporation, Sudan

Parasitoids of the genus Trichogramma are distributed world-wide and play an important role as natural enemies. To enhance the role of these beneficial insects, the side effects of various pesticides should be tested. In this study the duration of harmful activity (persistence) of 5 harmful pesticides in laboratory tests was carried out. Potted plants were sprayed to runoff using field recommended dose of tested pesticides. Leaves from tested plants were then removed at different periods and Trichogramma adults were exposed to these leaves in standard exposure cages. The percentage reduction in parasitism relative to the control was then measured. Confidor and Dicrazol remained harmful {International Organisation for Biological Control (IOBC) - Class 4} even 24 days after treatments. Chess was moderately toxic. Aztec and Masi were slightly toxic 24 days after treatment. The relationship between parasitism rate and time for various treatments were measured during the study. It was observed that correlation coefficient (R2) showed a clear trend. For the control it was less than 0.01, and for harmful pesticides it was less than 0.9, whereas for the others it was more than 0.9.

Effect of artificial nectars on survival of *Microctonus aethiopoides* (Hym.:Braconidae) parasitoid of *Hypera postica*(Col.:Curculionidae)

Abbas Arbab[1], Mark McNeill[2]

[1]*Islamic Azad University, Iran,* [2]*AgResearch, New Zealand*

Many parasitic wasps utilize floral resources, such as nectar to satisfy energy requirements for maintenance and reproduction. Floral nectar consists largely of carbohydrates (chiefly sucrose, glucose and fructose) and amino acids especially proline. The success of biological control is partly mediated by the longevity of beneficial insects and aavailability of nectar can improve the nutrition of parasitic insects, and thereby increase their longevity. Newly emerged wasps (<12h longevity) were feed singly whit 14 different solution presented on approximately 5 ×5 (mm) section of filter paper: the tap water (control), 2M glucose, 2M sucrose, 2M glucose+ fructose, 2M fructose, 2M clover honey, 2M sterile (heated) clover honey, water extracts of white clover leaf and flower and five combination of glucose (15%) and proline (0.05, 0.1, 0.25, 0.5, 5 %) to select the best of them. The experiment conducted in laboratory condition (20 ±1ºC, 14:10 L: D and 60±10% R.H.). Survival analysis was used to examine the effect of different diets on the longevity of M. aethiopoides. The product limit (Kaplan?Meier) method was used to estimate the survival distribution function in the analyses. The results indicated that in the male and female, between of carbohydrates, glucose have the most effect on longevity and also between of combinations of glucose and proline, the lowest concentrations (0.05 %) have a positive significant effect on longevity. While the highest concentration (5%) have a negative significant effect.

Effect of mass rearing of green lacewing, *Chrysoperla carnea* Stephens (Neu.: Chrysopidae) on growth rate index during multiple generations in

Mohammad Mohsen Montazeri[1], Mona Maghsoodlou[2], Saeed Ghadiri Rad[3]

[1]Gorgan branch, Islamic azad university, Iran, [2]Gorgan branch, Islamic azad university, Iran, [3]Agricultural and Natural Resources Research Center, Iran

Green lacewing, Chrysoperlacarnea Stephens is a polyphagous predator which used in inundation releases against a wide range of field and greenhouse insect pests, after mass rearing in insectarium. The main challenge in this method of biological control is the adverse effects of multiple reared generations of natural enemy under controlled conditions on its biological characters which may finally decrease pest control efficiency after field releasing. This experiment was designed and conducted in order to determine these adverse effects on a mass culture colony of green lacewing with collecting 570 adults from different regions of Golestan province. The stock was reared for 10 generations in insectarium of Agricultural and Natural Resources Research Center of Golestan. A mixture of yeast+sucrose (1:1) and eggs of the Angoumois Grain Moth (Sitotrogacerealella) were used as food for adults and larvae, respectively. Biological parameters including fecundity, pupalweight , percent of abnormal eggs,index growth ,length of egg,larva,pupa, preoviposition,adult and mortality of eggs,larva and pupal stage were measured for ten generations. Rates of adverse changes in these parameters were not equal. Deterioration start points with sharp decline for fecundity, pupal weight and percent of abnormal eggs and other changes were observed in 7th, 5th and 8th generations, respectively. Finally, in order to preserve predator vigor, it is recommended to limit insectarium cultures to 6th generation in similar conditions.

Sustainable management of *Spodoptera litura* by using *Bracon hebetor* and selective insecticides

Rashad Rasool Khan[1], Muhammad Ashfaq[2], Khuram Zia[3], Muhammad Dildar Gogi[4], Muhammad Arshad[5], Sohail Ahmed[6]

[1]University of Agriculture, Pakistan, [2]University of Agriculture, Pakistan, [3]University of Agriculture, Pakistan, [4]University of Agriculture, Pakistan, [5]University of Agriculture, Pakistan, [6]University of Agriculture, Pakistan

Armyworm, Spodoptera litura, is one of the most notorious polyphagous pests, attacking the cotton crop and hence depriving the farmers from getting good yields. The project under study, was, therefore, planned to develop some control strategies which are not only effective in their implementation, but also safer to the non-target organisms. For this purpose, a bio-control agent, Bracon hebetor (Say.) was used to control this notorious pest, along with the integration of some new chemistry insecticides throughout the cotton growing season. The insecticides under all the three conditions (Laboratory, semi-field and field) proved to be toxic for S. litura, but chlorpyrifos, profenofos, emamectin benzoate, spinosad, indoxacarb, methoxyfenozide and lufenuron proved to be highly toxic for the pest as the exposure time was extended. No insecticide in these experiments proved to be completely safe against the B. hebetor when the exposure time was extended but the above mentioned insecticides were comparatively safe than the remaining insecticides except chlorpyrifos and profenofos. The novel insecticides; emamectin benzoate, spinosad, indoxacarb, leufenuron and abamectin were safe for the parasitoid after short exposure time periods. These novel insecticides are therefore recommended for integration with the bio-control agent (Bracon hebetor). However, it is strongly recommended that the parasitoid should be released at least 24 hours after the application of these insecticides.

Azadirachtin based biopesticides influences insect head proteins in gram pod borer, *Helicoverpa armigera* Hubner (Lepidoptera: Noctuidae)

Dwijendra Singh

CSIR-Central Institute of Medicinal and Aromatic Plants, India

The demand of plant biopesticides have increased tremendously for integrated pest management and organic method of cultivation in arable crops because of harmful effects of synthetic pesticides. The azadirachtin, a tetranortriterpenoid obtained from Indian neem [Azadirachta indica A. Juss (Meliaceae)] is well known as potent phytogenic insect growth inhibitor to several insect orders namely Lepidoptera, diptera, orthoptera, hemiptera, coleopteran and hymenoptera etc. and commercialized extensively which have been found to influence the level of protein significantly in herbivores. The experimental result indicated that on average a 0.1 µg/ larvae dose of azadirachtin was found to reduce 30% in protein level up to 72 h in 7-day old larvae. However, the magnitude of reduction (23%) in 20 day-old larvae was found only 24 h after treatment in Helicoverpa armigera Hub. The results showed that azadirachtin decreased the total head protein of H. armigera in a dose-dependent manner. Besides, insect diet mixed with different azadirachtin-based formulations fed to fourth instars larvae of H. armigera also significantly ($P<0.05$) reduced the protein level. SDS-PAGE analysis of protein showed that azadirachtin suppressed 22, 26, 40 and 56 kDa head polypeptides in various treatments. Alternation in SDS polypeptide pattern was also observed with different modes of application in a dose dependent fashion. This information may be a novel basis of developing potential plant biopesticides based on screening protein estimation in relation to their bioactivities in future.

Natural plant compounds as insecticides for management of agricultural and veterinary pests

De Villiers Fourie[1], Schalk v.d.M. Louw[2], Seef Pretorius[3]

[1]University of the Free State, South Africa, [2]University of the Free State, South Africa, [3]University of the Free State, South Africa

Due to increased global awareness and concerns regarding the use of synthetic pesticides in general, as well as the direct and latent effect on the environment and severe insect population resistance problems, focus has shifted to alternative means of pest management. Among these strategies the use of natural plant derivatives as natural or botanical insecticides has emerged at the forefront of research. Several very successful botanical pesticides have been marketed thus far. At the moment, the worldwide demand for natural insecticides is increasing. Considering the ecological role of secondary plant products in plant-insect interactions, the strategy of isolating, identifying, and bioassaying these compounds seem to be an effective method of pesticide prospecting. The eventual aim of this study is to obtain viable moleculles for use as natural pesticides on several insect species of agricultural or veterinary importance. The active compounds of promising extracts will also be isolated and purified for accurate mapping. Initial bio-assays were conducted on stable flies, Stomoxys calcitrans (Diptera: Muscidae). These insects are fairly robust dipterans and important veterinary pests in their own right. The extracts of three promising plants, i.e. Zanthoxylum capense (Rutaceae), Agave attenuata (Agavaceae) and Dalbergia hupeana (Fabaceae), were examined for pesticidal efficacy. Efficacy trials were conducted on-site at the University of the Free State, with both Z. capense and A. attenuata emerging as very promising candidates for further testing. Currently, live colonies of various agricultural pests are being established, and further efficacy trials will be conducted as soon as colonies have become established.

Usage of Insecticide spraying equipment and protective measures by cocoa farmers in Nigeria

Ismaila Adeniran Aderolu[1], Uche E. Asogwa[2], M. Idrisu[3], I. Ndagi[4], I. U. Mokwunye[5], Folaranmi Dapo Babalola[6], F. C. Mokwunye[7]

[1]Cocoa Research Institute of Nigeria (CRIN)., Nigeria, [2]Cocoa Research Institute of Nigeria (CRIN), Nigeria, [3]Cocoa Research Institute of Nigeria (CRIN), Nigeria, [4]Cocoa Research Institute of Nigeria (CRIN), Nigeria, [5]Cocoa Research Institute of Nigeria (CRIN), Nigeria, [6]University of Ilorin, Nigeria, [7]Cocoa Research Institute of Nigeria (CRIN), Nigeria

The inappropriate use of cocoa pesticides and application equipment results in health and environmental hazard and development of insect biotypes. This study was carried out in three states of Nigeria using randomly administered questionnaires to thirty cocoa farmers in each state. The manual knapsack sprayer was found to be the widely used spraying equipment by the farmers. Despite their popular usage, only very few farmers (8% to 16.7%) used their graduated lid in the measurement of the insecticides. They rather preferred to use empty tin of evaporated milk (33.3% to 68%) or top cover of insecticide's bottle (24% to 50%) in the measurement of the insecticides into the knapsack. The farmers in all the selected states had different parts of the cocoa farms and/or plants that they preferred to spray and these ranged from the whole cocoa farm (29.2% - 40%) to part of the farm (16.7% -48%) to only affected trees (12% - 50%). Majority of the farmers (44% - 58.3%) did not comply with the use of necessary personal protective equipment (PPE) during spraying operations on their farms. A major challenge associated with cocoa farm spraying equipment as indicated by 70.8% to 80% of the farmers was high costs followed by lack of technical know-how to use the equipment as shown by 16.7% to 25% of the farmers. There is therefore an urgent need for massive training of the farmers on the practical use and maintenance of appropriate spraying equipment that are time saving and cost effective.

Evaluation of novel acaricide, cyflumetofen for management of tea red spider mite, *Oligonychus coffeae* Nietner

Gautam Chakraborty[1], Sabita Kumar Senapati[2]

[1]*Uttar Banga Krishi Viswavidyalaya (Ag. University), India,* [2]*Uttar Banga Krishi Viswavidyalaya (Ag. University), India*

Tea is grown in 15 states of India among these Assam is top with 50.7% of total production followed by West Bengal with 22.1%, Tamil Nadu 15.9% and Kerala 8.3%. However, it is estimated that 15-20% of the total crop is lost annual from the ravage of pests. More than 300 insects and mites are associated with tea plants among them, red spider mite, Oligonychus coffeae (Nietner) is on the verge of the assuming the status of key pest on tea and along can damage more than 5-15% of the total crop in several specific geographical locations of West Bengal. To protect the crop, pesticides are in use since long back but pest species are now showing less susceptibility to some age old pesticides and also develop resistance. Hence, it has become important to search out new acaricide that will be selective in action against the mite, less toxic to beneficial arthropods, free for health hazards and also safe to environment. Studies were made to evaluate bio-efficacy and phytotoxicity of cyflumetofen a novel highly selective acaricide and causes paralysis and death, along with some new acaricides against tea red spider mite under field conditions. The experiment was carried out at terai region of West Bengal, India. Cyflumetofen 20%SC having good cidal effects on different stages of life cycle of tea red spider mite without showing any phytotoxicity symptoms on tea plants and safe for environment. So, it may be incorporated in IPM programme.

Insecticidal efficacy of *Beauveria bassiana* (Balsamo) Vuillemin mixed with diatomaceous earth against *Rhyzopertha dominica* F.

Tahira Riasat[1], Naureen Aziz Qureshi[2], Waqas Wakil[3], Yong Jung Kwon[4]

[1]G.C. University, Faisalabad, Pakistan, [2]G.C. University, Faisalabad, Pakistan, [3]University of Agriculture, Faisalabad, Pakistan, [4]Kyungpook National University, Republic of Korea

The effects of mixing Beauveria bassiana (Balsamo) Vuillemin (1.7 x 104, 1.7 x 106 and 1.7 x 108 conidia kg-1 of grains) with diatomaceous earth (DE) formulation SilicoSec (100 ppm) against two populations of Rhyzopertha dominica F. (Coleoptera: Bostrychidae) were assessed. The trials were conducted on wheat grains at 30oC and 65% rh and the mortality of R. dominica adult was calculated 5, 10 and 15 d after exposure. The progeny production was observed from the treated units held for 60 d. Reseults revealed significant differences in adult mortality among populations and combined use of B. bassiana and DE increased adult mortality which was directly related with dose rate and exposure interval. The combined treatment was least effective against Bahawalpur population and most effective against Toba Tek Singh population of R. dominica. The reduced emergence of progeny was observed where B. bassiana and DE was combined at their higher dose rates. The data about the mycosis and sporulation revealed the maximum rate of mycosis and sporulation in cadavers of R. dominica where the low dose rates of B. bassiana were applied. The results of the present work suggest that the effectiveness of B. bassiana could be enhanced by the addition of DE, but the efficacy varies among populations.

Keywords:*B. bassiana, SilicoSec, R. dominica, progeny, mycosis, sporulation*

Efficacy of safer insecticides against aphid on celery

Ravinder Singh Chandi[1], B. S. Gill[2]

[1]Punjab Agricultural University, Ludhiana-141 004, Punjab, India, India, [2]Punjab Agricultural University, Ludhiana-141 004, India

Celery plant (Apium graveolens) is cultivated for its fleshy leafstalks and seeds which yield essential oil. Aphids (Myzus persicae) suck sap from plant and reduce yield. Also they transmit viral diseases and contaminate celery produce with honeydew. Some safer insecticides namely Flonicamid 50 WG @ 150, 175 and 200 g/ha, Imidacloprid 200 SL @ 75, 100 and 125 ml/ha, Thiamethoxam 25 WG @ 75, 100 and 125 g/ha and Acetamiprid 20 SP @ 37.5, 50 and 62.5 g/ha were tested for their efficacy. Population of aphids per inflorescence before spray varied from 12.30 to 16.97. On third and seventh days after spray (DAS) Flonicamid @ 175 and 200 g/ha, Imidacloprid @ 100 and 125 ml/ha, Thiamethoxam @ 100 and 125 g/ha, Acetamiprid @ 62.5 g/ha were statistically better in reducing aphid population than other treatments. On tenth DAS 100 per cent mortality was observed in Flonicamid @ 200 g/ha, Imidacloprid @ 100 and 125 ml/ha, Thiamethoxam @ 100 and 125 g/ha and Acetamiprid @ 62.5 g/ha and these were statistically at par with Acetamiprid @ 50 g/ha and Flonicamid @ 175 g/ha. In standard checks Malathion 50 EC @ 1000 ml/ha only 55.50 per cent mortality was observed. Highest population of natural enemies mainly ladybird beetle was recorded in the plots sprayed with Flonicamid. Highest seed yield of 12.7 q/ha was obtained with Flonicamid @ 200 g/ha which was statistically at par with Imidacloprid @ 100 and 125 ml/ha, Thiamethoxam @ 100 and 125 g/ha and Acetamiprid @ 62.5 g/ha.

Coadministration of wax dissolving agents with insecticides: An effective toxicity enhancing approach for the chemical control of adult female and ovisac stages of *Phenacoccus solenopsis*

Muhammad Dildar Gogi[1], Muhammad Jalal Arif[2], Muhammad Hamid Bashir[3], Muhammad Ahsan Khan[4], Muhammad Faheem Akhtar[5], Adeel Mukhtar[6], Muhammad Nauman[7]

[1]University of Agriculture, Faisalabad, Pakistan, Pakistan, [2]University of Agriculture, Faisalabad, Pakistan, Pakistan, [3]University of Agriculture, Faisalabad, Pakistan, Pakistan, [4]University of Agriculture, Faisalabad, Pakistan, Pakistan, [5]University of Agriculture, Faisalabad, Pakistan, Pakistan, [6]University of Agriculture, Faisalabad, Pakistan, Pakistan, [7]University of Agriculture, Faisalabad, Pakistan, Pakistan

Adult female and ovisac stages of Phenacoccus solenopsis are very difficult to manage with synthetic insecticides because these stage life stages are protected by either thick waxy covering (adult female) or by the fluffy ovisac (ovisac stage). The biofactors of insect life help the pest ovoid the insecticide exposure and develop overlapping generations inspite of chemical application. The toxicity enhancing approach evaluated in the laboratory during present studies implied the coadministration of various wax dissolving agents with such insecticides which proved ineffective alone against adult female and ovisac stages of P. solenopsis. Wax dissolving agents in different combinations were evaluated in the laboratory alone or in coadministration with insecticides by topical application method. After topical application, ten specimens of respective treated stage of P. solenopsis were released inside the sterilized petridish having untreated pieces of pumpkin bottom part and sieved hole in the lid part of petridish which were then put inside the incubator maintained at 30±1 ºC and 65±5% rh. This approach synergized the toxicity of insecticide many fold enhancing the mortality of adult stages by many fold removal of wax and accelerated dehydration from the body as well as of ovisac stage by dissolving the fluffy ovisac and exposing the ovisac stage to insecticide contact. This approach would be a turning point in the chemical management of P. solenopsis. The details of the rest of results are discussed in the present manuscript.

Pyrifluquinazon: A novel insecticide for managing *Bemisia tabaci* and transmission of *Tomato Yellow Leaf Curl Virus*

Mariappan Suganthy[1], Srinivasan RajagopalBabu[2], Stan Diffie[3], Anita Shrestha[4]

[1]Tamil Nadu Agricultural University, Coimbatore, Tamil Nadu, India, [2]University of Georgia, Tifton, U.S.A., [3]University of Georgia, Tifton, U.S.A., [4]University of Georgia, Tifton, U.S.A.

Pyrifluquinazon a novel insecticide developed by Nihon Nohyaku Co., Ltd, Japan is used to control aphids, thrips, mealybugs and scale. Glasshouse studies were conducted at Department of Entomology, University of Georgia, Tifton to determine the efficacy of pyrifluquinazon in controlling Bemisia tabaci and in preventing acquisition and transmission of the begomovirus Tomato yellow leaf curl virus (TYLCV). Regarding settling behaviour of B. tabaci in pesticide treated plants, newer molecules like pyrifluquinazon and cyazypyr harboured minimum number of whiteflies. Efficacy of pyrifluquinapon on acquisition of TYLCV by B. tabaci showed that whiteflies caged in all the treated infected plants acquired the virus and were statistically on par in their acquisition rate. But, the whiteflies that were positive to TYLCV by PCR, died after feeding on the treated plants. Among the pesticide treated plants, viruliferous whiteflies fed on imidacloprid treated healthy plants could able to transmit TYLCV upto 10%. While, viruliferous whiteflies fed on pyrifluquinazon, cyazypyr and pymetrozine treated healthy plants could not be able to transmit TYLCV. Studies on efficacy of newer pesticide molecules on primary spread of TYLCV registered that among the treatments, viruliferous whiteflies fed on imidacloprid treated plants transmitted 31.9 per cent TYLCV infection followed by pymetrozine (12.5%), pyrifluquinazon (6.3%) and cyazypyr (6.3%). Whiteflies fed on untreated control resulted in 100 per cent TYLCV infection. These data justify inclusion of this novel insecticide with a new mode of action for foliar application in TYLCV management program.

To determine the yield losses, caused by aphids in canola *Brevicoryne brassicae, Myzus persicae, Lipaphis erysimi* under field conditions in organic and inorganic systems of farming.

Muhammad Jalal Arif[1], Qaisar Abbas[2], Muhammad Dildar Gogi[3], Hussnain Ali Sayyed[4], Muhammad Ashfaq[5]

[1]University of Agriculture, Faisalabd, Pakistan, [2]University of Agriculture, Faisalabd, Pakistan, [3]University of Agriculture, Faisalabd, [4]University of Agriculture, Faisalabd, Pakistan, [5]University of Agriculture, Faisalabd, Pakistan

Canola brassica napus is subject to attacked by various invertebrate pest all over the world (Lamb 1989). At least 30 species of invertebrates' pest have been found feeding on canola plants.There are three major aphid species infesting the canola crop, those are cabbage aphid, Brevicoryne brassicae (L.), the turnip aphid, Lipaphis erysimi Kalt, and the green peach aphid, Myzus persicae (Sulzer) (Hemiptera: Aphidae).Normally an aphid causes 30-35% yield loss on brassica plant, but if it is not controlled yield loss may rise up to 70%. The study was carried out in the farm area of university of agriculture, Faisalabad to determine the yield losses caused by aphids in canola crop. Canola crop was grown by organic and inorganic farmings. Seeds were sown with hand drill in a plot having three rows, with row to row distance 0.5m and plot to plot 1.5m. After germination cultural practices were performed through out the growing season uniformly in all plots. Aphids were allowed to develop on two rows, where as one row was kept free from aphids by spraying insecticides advantage in each treatment. During the application of insecticides, it was make sure that insecticides may not affect the aphids present on plants of remaining rows. There were negligible aphids on treated lines. Plants were inspected regularly for aphid population in all plots.

Bio-Activity of *Secamone afzelii* (Schult) extracts for the management of beetles on stored cowpea seeds

Jacobs Mobolade Adesina[1], Tom I. Ofuya[2]

[1]Rufus Giwa Polytechnic, Nigeria, [2]Federal University of Technology, P. M. B. 704, Akure, Ondo State, Nigeria

Insect damage of stored grains and pulses may amount to 10-40% in countries where modern technologies have not been introduced. The efficacy of oil extracted from leaves of Secamone afzelii was evaluated in the laboratory against Callosobruchus maculatus attacking stored cowpea. Leave extracts from Secamone afzelii was obtained by soxhlet extraction method using ethanol and hexane as the solvent. Each of the extracts was tested by exposing five pairs adult beetles to various levels of 0.5, 1.0, 1.5 and 2.0ml corresponding to 2.5, 5.0, 7.5 and 10.0% v/w admixed with 20g cowpea in three replications respectively in a Completely Randomized Design (CRD). Control treatment was set along. The result indicated that all the leaf extracts treatments recorded significantly high ($P<0.05$) adult mortality at 48 and 72 hours after treatment. oviposition of the female beetles was significantly reduced on seed treated with higher treatment level of extracts, in comparison with control. The extracts reduced the F1 progeny emergence, adult exit hole and percentage weight loss. However, among leaf extracts, ethanol leaf extract at 2ml (10.0% v/w)/20g cowpea seeds was most effective in reducing female oviposition and seed damage. Therefore, the extracts has great potential for use as a plant-based biopesticide for controlling pulse beetle C. maculatus.

Prey suitability, population growth and development of*Orius maxidentex* Ghauri (Hemiptera: Anthocoridae)

Athitiya Kaewpradit[1], Oraphan Kernasa[2], Wiwat Suasaard[3], Anuchit Chinajariyawong[4]

[1]National Biological Control Research Center (NBCRC), Thailand, [2]Agricultural at Kamphaeng Saen, Kasetsart University Kamphaeng Saen Campus, Nakhon Pathom, Thailand, [3]Agricultural at Kamphaeng Saen, Kasetsart University Kamphaeng Saen Campus, Nakhon Pathom, Thailand, [4]National Biological Control Research Center (NBCRC), Thailand

Laboratory studies on the biological information of the anthocorid predator, Orius maxidentex Ghauri was conducted. Firstly, prey preferences were done in choice and non-choice tests on four species of prey including Thrips palmi Karny, Aphis gossypii Glover, Bemisia tabaci Gennadius, and Tetranychus truncates Ehara. Both nymphs and adults of O. maxidentex preferred T. palmi to the other three species. In addition, 1st and 2nd instar nymphs of the predator did not consume A. gosypii. Subsequently, the life-table parameters of O. maxidentex were obtained only in T. palmi and B tabaci; because no nymphs survived to adults when fed with A. gossypii, and T. truncates. The net reproductive rate of increase (Ro, /) was higher when provided the predator with T. palmi (2.6200) than with B tabaci (0.6850); and the cohort generation time (Tc, day) 17.4200 and 16.5180; the capacity of increase (rc, / /day) 0.0553 and -0.0229; and the finite rate of increase (λ, / /day) 1.0568 and 0.9773, respectively. Finally, the life cycle of O. maxidentex fed with P. palmi revealed the incubation period of egg 3.26+0.44 days; the total nymphal development duration, 1st - 5th instars, 13.79+1.26 days. The means longevity of adult male and female were 7.95+1.39 and 9.31+2.51 days, respectively and with a sex ratio : 1:1.39. Hence, T. palmi was the suitable prey among the test species for mass production of O. maxidentex. A total number of 30,000 adults/month of the predator were mass-produced.

Biological control strategies against Lepidopteran pests by using egg parasitoids

Elisabeth Tabone

INRA - Nice 400 route des Chappes, 06903 Sophia Antipolis, France

Development of biological control strategies by using egg parasitoids has been performed for many years at INRA in the South of France. Each biological control program needed to be studied through some key steps, as following: 1.Pest studies and damage 2.Study of beneficial insects 3.Screening of parasitoid efficacy in laboratory, mesocosm,... 4.Release strategies of parasitoids 5.Optimization of field releases in crops 6.Optimization of mass production 7.Checking of field efficacy 8.Agro-system management and ecological effects Step by step, important programs on biological control against Lepidopteran pests by inundative releases of Trichogramma spp. were performed in our laboratory, thanks to large collaboration, against: ?Paysandisia archon, castniid palm borer (2012-2013), invasive pest in Mediterranean Bassin and Europe ?Tuta absoluta, tomato leafminer by studying about 100 strains of Trichogramma (2011-2013). Parasitoid efficacy in laboratory, mesocosme, greenhouse or in field has been evaluated, then compared to the control strain of Trichogramma achaeae, species currently marketed. ?Chilo sacchariphagus, stemborer of sugarcane : IPM strategy reduced up to 50% of damage with financial gains ranging from 800 to 1800 dollars per ha (associating inundative release of an egg parasitoid, Trichogramma chilonis and conservation of a predatory ant, Pheidole megacephala) (since 2000) ?Cacyreus marshalli, geranium bronze butterfly by studying 8 species of Trichogramma spp. (2000-2001) ?Plutella xylostella, diamondback moth (on cabbage) by using Trichogramma spp. (1998-2000) Sharing experiences and advances obtained these diverse research programs seems interesting for other projects by biological control and for the scientific community.

Biological control against the tomato leafminer, *Tuta absoluta*, by studying egg parasitoids to improve IPM strategies

Hong Do Thi Khanh[1], Marion Tiradon[2], Anais Chailleux[3], Nicolas Desneux[4], Etty Colombel[5], Gilles Ridray[6], Frederic Rey[7], Anais Vernillet[8], Julien Seguret[9], Pascal Maignet[10], Yannie Trottin - Caudal[11], Catherine Chabriere[12], Jerome Lambion[13], Anne Terrentroy[14], Elisabeth Tabone[15]

[1]INRA - Nice, France, [2]INRA - Nice, France, [3]INRA - Nice, France, [4]INRA - Nice, France, [5]INRA - Nice, France, [6]INRA - Alenya, France, [7]ITAB - Paris, France, [8]Biotop - Valbonne, France, [9]Biotop - Valbonne, France, [10]Biotop - Valbonne, France, [11]CTIFL Balandran, France, [12]APREL, France, [13]GRAB Avignon, France, [14]Chambre d'Agriculture des Bouches-du-Rhone, France, [15]INRA - Nice, France

Since 2011, new egg parasitoids have been studied in our research program improving IPM strategies against Tuta absoluta, the South American tomato leafminer (TutaPI program, French funding, 2011-2013). This invasive pest in Mediterranean Basin and Europe may cause serious damage on tomato crops without efficient control methods. Greenhouse tests in IPM strategies combining inundative releases of Trichogramma achaeae (a commercially-available species) and the predator, Macrolophus pygmaeus, were efficient. This predator is also used against whiteflies on protected tomato crops. Other species of Trichogramma (19) from the whole world were investigated. Firstly, screening of parasitoid efficacy was performed in the laboratory for sixty-four strains (long-term rearing in the laboratory in the collection at INRA Provence-Alpes Cote d'Azur, France). Then, thirty strains collected last summer (from tomato crops in the South of France, collections performed by TutaPI partners) were studied. In laboratory conditions, some strains from both long-term rearing and field collections showed better efficacy than the control strain Trichogramma achaeae. The parasitoid efficacy is being studied in mesocosm, then in greenhouse to select the most efficient strains for biological control and IPM strategies. This work combined with other actions within the TutaPI program, aims to develop IPM strategies that are more efficient and at an affordable cost to growers.

Interspecific competition of parasitoids of *Bactreara dorsalis*(Hendel)

Jiahua Chen[1], Minlin Zheng[2], Qinge Ji[3]

[1]Fujian Agriculture and Forestry University, China, [2]Fujian Agriculture and Forestry University, China, [3]Fujian Agriculture and Forestry University, China

Oriental fruit fly, Bactrocera dorsalis (Hendel) , is one of the most serious pests in China. It damages more than 250 species of fruits and vegetables belong to 40 families. Fopius arisanus (Sonan), Psyttalia incisi (Silvestri), Fopius vandenboschi (Fullaway) and Diachasmimorpha longicaudata (Ashmead) are the famous parasitoids of B.dorsalis in the world and they can attack eggs and different instars of the host. In order to control B. dorsalis effectively by parasitoids, the interspecific competitions of the 4 parasitoids were studied under laboratory conditions. The results showed that the larvae parasitoids P. incise and D. longicaudata could not discriminate the hosts which had been parasitized at egg stage by egg parasitoid F. arisanus but F. vandenboschi could. The D. longicaudata could discriminate the hosts which had been parasitized at young larva stage by P. incisi but not by F. vandenboschi. P. incisi and F. vandenboschi could not discriminate each other, but the success depended on the first.

Investigations into diploid males in the *Wolbachia*-infected parasitoid, *Trichogramma kaykai* Pinto & Stouthamer (Hymenoptera: Trichogrammatidae)

Genet M Tulgetske[1], Richard Stouthamer[2]

[1]*University of California, Riverside, U.S.A.*, [2]*University of California, Riverside, U.S.A.*

Sex determination in the haplodiploid order, Hymenoptera, has been studied extensively but is still not well understood. While cytoplasmic and environmental factors have been shown to influence sex determination in the Hymenoptera, the genetic mechanism, Complementary Sex Determination (CSD), is the only well understood mechanism of sex determination in this order. However, CSD does not explain sex determination in members of the superfamily, Chalcidoidea. In the chacidoids, temperature and cytoplasmic reproductive parasites, such as Wolbachia, may significantly affect sex determination. Female Trichogramma parasitoids infected with parthenogenesis-inducing (PI) Wolbachia typically produce exclusively diploid homozygous female offspring. However, these wasps can produce a small number of intersex and male offspring when exposed to high temperatures during late larval/ early pupal development. We examined 142 males produced by Wolbachia infected Trichogramma kaykai females using flow cytometric analysis and determined approximately 6% percent of were diploid. Further examination into the reproductive function of parthenogenetically produced diploid males showed that diploid males experience significantly reduced reproductive success than their haploid counterparts. However some diploid males are at least partially fertile and sire triploid females, presumably with unreduced sperm. These findings may provide valuable insight into the mechanisms governing chalcidoid sex determination as well as the methods by which reproductive parasites are able to manipulate sex in this group.

Sugar as nutritional supplement for the zoophytophagous predator *Nesidiocoris tenuis*: Practical implications

Pablo Urbaneja-Bernat[1], Miquel Alonso-Valiente[2], Oscar Molla[3], Karel Bolckmans[4], Alejandro Tena[5], Alberto Urbaneja[6]

[1]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain, [2]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain, [3]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain, [4]Koppert B.V. Veilingweg 17. 2651 BE Berkel en Rodenrijs., Netherlands, [5]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain, [6]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain

Nesidiocoris tenuis (Reuter) (Hemiptera: Miridae) is a zoophytophagous predator widely used in integrated pest management programs in both, greenhouse and open-field, tomato crops in the Mediterranean basin. Its use, both by inoculation or conservation, may cause some drawbacks. First, to establish N. tenuis, inoculative releases are usually combined with the addition of Ephestia kuehniella Zeller (Lepidoptera: Pyralidae) eggs. The use of this factitious prey increases the cost of the release. Second, N. tenuis can cause some plant damage due to its phytophagous diet when prey is scarce. The aims of this work were: (i) to evaluate the effect of sugar addition on the biology and prey consumption of N. tenuis under laboratory conditions; (ii) to test whether the quantity of E. kuehniella eggs added as factitious prey could be reduced when sugar sources were also added under greenhouse and open-field conditions; (iii) to test whether the addition of sugar reduce the damages inflected by N. tenuis. Our results showed that the addition of sugar in an E. kuehniella-based diet increased N. tenuis progeny and reduced the predation rate of E. kuehniella eggs. In the field, the addition of sugars reduced the number E. kuehniella eggs necessary to establish N. tenuis and reduced the damage produced by N. tenuis. These findings may have practical implications, both in N. tenuis mass-rearing systems and in biological control programs where N. tenuis is released.

Comparative study of suitable host plants for adult oviposition and hatching ability of the predatory bug, *Wollastoniella rotundai* (Hemiptera: Anthocoridae)

Anuchit Chinajariyawong[1], Tewee Maneerat[2], Dokgluaymai Homrahud[3], Wiwat Suasaard[4]

[1]National Biological Control Research Center (NBCRC), Thailand, [2]National Biological Control Research Center (NBCRC), Thailand, [3]National Biological Control Research Center (NBCRC), Thailand, [4]Agricultural at Kamphaeng Saen, Kasetsart University Kamphaeng Saen Campus, Nakhon Pathom, Thailand

Wollastoniella rotunda Yasunaga & Miyamoto (Hemiptera: Anthocoridae) is an important natural enemies of tiny insect pests, especially thrips, Thrips palmi Karny. Mass rearing of natural enemies is crucial for biocontrol agents release. The objective of the study was to investigate the suitable host plants for the predator to lay most eggs and their hatching ability. The experiment was assigned in a completely randomized design with 20 replications. Seven species of plants were tested; they were two-month old eggplant plant, one-month old eggplant, sprouts of mungbean, blackbean, soybean, red kidney bean and peanut. Adults of W. rotunda did not survive when reared on sprouts of soy bean, red kidney bean and peanut. But they survived and reproduced on eggplant plants (both one- and two-month old), sprouts of mungbean and black bean. Number of eggs laid/plant/day were not statistically different ($P>0.05$) among two-month old eggplant plant (4.05±2.35), one-month old eggplant (5.05±3.71) and black bean sprout (4.30±3.10) but they were statistically different ($P<0.05$) from mungbean sprout (2.55±1.47). Furthermore, hatching percentage of eggs on two-month old eggplant plant (90.00±30.78) was statistically different ($P<0.05$) from one-month old eggplant (45.52±35.39), mungbean sprout (44.67±40.79) and black bean sprout (44.87±35.50). Consequently, two-month old eggplant was the most suitable host plants among the test plants, for initiating new culture of the predators.

Effects of temperatures on shelf life of cocoon and adult survival for transportation of *Cotesia flavipes* (Cameron) (Hymenoptera: Braconidae)

Tewee Maneerat[1], Wiwat Suasaard[2], Anuchit Chinajariyawong[3]

[1]National Biological Control Research Center (NBCRC), Thailand, [2]Agricultural at Kamphaeng Saen, Kasetsart University Kamphaeng Saen Campus, Nakhon Pathom, Thailand, [3]National Biological Control Research Center (NBCRC), Thailand

Infestations of the lepidopteran sugarcane borer complex, Sesamia inferens (Walker), Chilo tumidicostalis Hampson, Chilo sacchariphagus (Bojer) and Chilo infuscatellus (Snellen), the most important pest insects of Thailand sugarcane plantations, occur annually. Two consecutive field experiments were performed with Cotesia flavipes (Cameron), a braconid biocontrol agent of the pest, in Central Thailand, with two objectives: to optimize rate and timing of field release of C. flavipes in order to suppress the pest infestations and to maximize the yield of sugarcane. Demonstration sites, in each experiment, were done in four field locations, two acres at each site, and in completely randomized block design. Results in the first experiment came out with the higher rate of release, the higher percent parasitisation obtained. With 375 and 500 adults release/acre yielded 22.48±4.03 and 25.12±3.77% parasitisation which were significantly higher ($P<0.05$) than those release with 125, 250 adults/acre and in control treatment (non-release), 14.81±4.11, 17.16±3.37 and 2.56±1.47, respectively. However, percent parasitisation in treatments, 375 and 500 adults/acre, were not significantly different ($P>0.05$). Later experiment, timing of release, with 375 adults/acre, appeared that monthly release of the parasites in 1-month old sugarcane sprouts gave 25.46±2.13% parasitisation and the sugarcane yield was 38.38 tons/acre which were significantly higher ($P<0.05$) than those in treatments, monthly release in 4-month old sugarcane; monthly release in 4-month old plus cut-off the insect-damaged shoots of sugarcane; and control (non-release). Percent parasitisation in the four later treatments were 21.42±4.31, 25.46±2.13, 21.48±2.00, and 6.20±0.91; and yields gained were 13.55±0.83, 14.68±0.37, 13.48±0.87 and 10.63±1.22 tons/hectare, respectively.

Influence of abiotic factors on the parasitism rate of *Platygaster diplosisae*, Risbec and *Aprostocetus procerae*, Risbec on African rice gall midge (*Orseolia oryzivora*, Harris & Gagne)

Emmanuel Omogo Ogah[1], Francis E. Nwilene[2]

[1]*Ebonyi State University, Nigeria,* [2]*Africa Rice Center, IITA Ibadan, Nigeria*

African rice gall midge (AfRGM), Orseolia oryzivora is one of the most damaging insect pests of lowland rice in Nigeria in the recent time, and could result in total crop failure in endemic areas. Of all the control measures adopted so far biological control is the most promising. Two parasitoids (Platygaster diplosisae, Hym: Platygastridae and Aprostocetus procerae, Hym: Eulophidae) have been identified with the potential to suppressed AfRGM population. In the current study, we evaluated the effect of abiotic factors (rainfall, relative humidity and temperature) in two eco-sites for two years on the the efficiency of the two parasotioids in the management of AfRGM. Percentage parasitisms by the two parasitoids were found to have significant correlation with the abiotic factors. Heavy rains and high humidity significantly reduced the efficiency of the two parasitoids. On the contrast, the population and efficiency of the parasitoids were observed to increase with reducing rainfall, RH, but increasing temperature thus increasing the efficiency of the parasitoids later in the season with up to 70% parasitism when combined, with P. diplosisae dominating the field. The results suggest that abiotic factors played significant role on the efficiency of these parasitoids and should be considered in the adoption of these parasitoids as bio-control agents of AfRGM.

A classical biological control program against Pseudococcus comstocki (Hemiptera: Pseudococcidae) has been started in France in 2008. In this program, we have guided each step with genetic characterisation methods. First, we used DNA-sequencing to compare P. comstocki populations worldwide and identify their natural enemies. Second, we set up rapid PCR-based identification tools to support field surveys. Third, we developed microsatellite markers for the biocontrol agents Acerophagus malinus (Hymenoptera: Encyrtidae) and Allotropa burrelli (Hymenoptera: Platygastridae) and currently use them to characterise the populations to be field-released. This program is a good opportunity to evaluate the actual interests of using genetic methods. Indeed, although widely advocated, their use in routine is challenging: they must be set and used fast enough to provide relevant information when decisions are needed and must be at least as cost-efficient as other methods. Overall, the methods tested proved useful. DNA-sequencing avoided misidentification of P. comstocki with closely related taxa in several collection sites and allowed fast recognition of natural enemies without systematically sending specimens to taxonomists. PCR identification tools proved helpful to select future release sites because they allowed easy identification of field-collected mealybugs (as several species are often found in same agrosystems). Finally, although microsatellites are still under evaluation, they already successfully revealed loss of genetic diversity or detected between-populations contaminations in rearings. However, we still do not have strong evidence of a positive relationship between genetic diversity at microsatellite markers and performances displayed by the biocontrol agent populations.

New host record for the egg parasitoid *Anagrus atomus* (Hymenoptera: Mymaridae) of the corn leafhoppers, *Z. sohrab, E. decipiens, A. decedens, P. striatus* (Hemiptera: Cicadellidae) and its population

Cetin Mutlu[1], Erdal Sertkaya[2]

[1]Plant Protection Research Station of Diyarbakır, Turkey, [2]Plan Protection Department, University of Mustafa Kemal- Hatay, Turkey

This study was carried out in order to determine the egg parasitoids of the four leafhopper species, which are the most abundant and common, at main and second crop maize cultivated areas in the South East Anatolia Region in 2009. Also the parazitoid was monitored its population fluctuation both main and second crop maize field in Diyarbakir province in 2010-2011. To obtain the egg parasitoids of the leafhoppers was used three different methods at laboratory and natural condition. Leaf samples infested with the leafhopper eggs were collected to observe its population fluctuation every week from the maize fields during vegetation. At the end of this study, only one dominant parazitoid species, Anagrus atomus (Linnaeus) (Hym.: Mymaridae), was determined. This is the first reference and record of this parasitoid reared from the eggs (Z.sohrab, E.decipiens, A.decedens and P.striatus) of the corn leafhoppers in Turkey. The parasitization rates were not measured because of rotting or dessication of some leaves containing exposed eggs. The population of A. atomus began to rise at beginning 2-4 leaf stage and reached to highest level at the maturation stage with parallel of the pests population development at main crop maize (on August) in both two years. Similarly results have been observed at second crop maize; the population of A.atomus has reached to highest level at flowering stage (on August).

Choosing predators for biocontrol of Colorado potato beetle in the South Ural

Konstantin Kitaev[1], Maxim Udalov[2], Galina Benkovskaya[3]

[1]Institute of biochemistry and genetics of Ufa Scientific Center of Russian Academy of Sciences, Russia, [2]Institute of biochemistry and genetics of Ufa Scientific Center of Russian Academy of Sciences, Russia, [3]Institute of biochemistry and genetics of Ufa Scientific Center of Russian Academy of Sciences, Russia

Invasive species are the most problem in ecology. Trophic relationships of invasive species are very important for designing methods of pest management and biocontrol. We are researching the adaptation processes in predators proceeding to feed by Colorado potato beetle (Leptinotarsa decemlineata Say) in the South Urals. This species is invasive. It has appeared in South Urals 34 years ago. Complex of predators living in potato field is formed since its arrival Predatory insects were caught in antifreeze (water solution of ethylenglicol) and were preserved for a week. We extracted DNA from gut and its content; also we extracted DNA from other tissues (muscles, fat body). These samples of DNA were used for PCR with specific primers designed from COI of L. decemlineata. Predation in the insects can be detected by PCR analysis with species-specific primers even through 24 hours. Several species of Carabidae and Coccinellidae were caught. Seven-spotted lady beetle (Coccinella septempunctata L.), Pterostichus melanarius Ill., Harpalus rufipes De Geer and Calosoma investigator Ill. are most abundant predators in potato fields. The most positive results of PCR - analysis of predators gut content have been given in the case of C. septempunctata. Investigation funded RFBR (grant No 11-04-97022-r_povolzhie_a).

Introduction of *Anagyrus lopezi* for biological control of the pink cassava mealybug, *Phenacoccus manihoti*, in Thailand

Amporn - Winotai[1], Prapassorn - Choeikamhaeng[2], Rojana - Waijaroen[3], Chalida - Unahawutti[4], Patchareewan Maneesakorn [5]

[1]Plant Protection Research and Development Office, Entomology and Zoology Group, Thailand, [2]Plant Protection Research and Development Office, Entomology and Zoology Group, Thailand, [3]Plant Protection Research and Development Office, Entomology and Zoology Group, Thailand, [4]Plant Protection Research and Development Office, Entomology and Zoology Group, Thailand, [5]Entomology and Zoology Group, Thailand

The Pink cassava mealybug, Phenacoccus manihoti was first reported in Thailand in 2008 and by 2009 more than 230,000 hectares were infested. Chemical controls were attempted but could not contain the pest. Intensive surveys found no effective natural enemies. In West Africa, Anagyrus lopezi was reported as the most effective biological control agent of this mealybug. Five hundred adults of A. lopezi were introduced from International Institute of Tropical Agriculture, Benin by the Thai Department of Agriculture in September 2009. Host specificity testing showed the parasitoid attacked only P. manihoti and was safe for use as biological control agent in Thailand. Procedures for mass rearing of the parasitoids were developed and used mealybugs reared on cassava plants. Later rearing of mealybugs was on pumpkins which reduced the cost of parasitoid production. After obtaining a Release Permit, field releases started in July, 2010. 300 pairs of A. lopezi wasps per hectare were recommended for release on mealybug-infested cassava, but where heavy infestations occurred, 1250 pairs per hectare were recommended. Training courses were organized for transferring technologies to DOA researchers, extension officers and technicians of private sector. A total of 44 parasitoid rearing units were established at government and private sector facilities. Through this cooperative effort, more than 15,600,000 pairs of A. lopezi were released during 2010-March 2012 and as a result the outbreak areas were reduced to 4,190 hectares or 8.9% of total growing area, thus helping the cassava farmers and saving the Thai tapioca industry.

Biological control of the millet head miner *Heliocheilus albipunctella* De Joannis (Lepidoptera: Noctuidae) by augmentative releases of the parasitoid wasp *Habrobracon hebetor* Say (Hymenoptera: Braconi)

Malick Niango Ba[1], Ibrahima Baoua[2], Mamadou Ndiaye[3]
[1]*INERA, Burkina Faso,* [2]*INRAN, Niger,* [3]*IER, Mali*

The pearl millet, (Pennisetum glaucum) production one of the most important staple crop in the Sahelian region is threaten by damages of insect pest. The millet head miner (MHM) Heliocheilus albipunctella (de Joannis) (Lepidoptera: Noctuidae), is one of the most important insect pests. Its developing larvae feed on the panicle and prevent grain formation. Among management strategies, biological control is one of the most promising methods. A biological control program was developed using an endogenous larval ecto-parasitoid wasp Habrobracon hebetor Say. The program was experimented in Burkina Faso, Mali and Niger from 2006 to 2009 by augmentative releases of the parasitoid. Parasitoids were allowed to reproduce and multiply in jute bags from which their offspring were able to escape through the jute meshes and dispersed to parasitize the MHM larvae in millet field. Our results indicate that up to 80% of H. albipunctella larvae were killed after releases of the parasitoids. As a result, damages of the MHM were reduced. This biological control program covered over 400 villages in the three countries and was positively perceived by farmers. Results are discussed in the perspective of sustainability and improvement of the program.

Biological activities of emamectin benzoate and spinosad against *Trogoderma granarium*

Sohail Malik Akhtar[1], Mansoor ul Hasan[2], Muhammad Sagheer[3], Shahzad Saleem[4]

[1]University of agriculture faisalabad pakistan, Pakistan, [2]University of agriculture faisalabad pakistan, Pakistan, [3]university of agriculture faisalabad pakistan, Pakistan, [4]University of agriculture faisalabad pakistan, Pakistan

The present project was designed to evaluate the efficacy of spinosad and emamectin benzoate against Trogoderma granarium under the laboratory condition following completely randomized design. The experiment was carried out to check direct mortality and population build up. Patri dishes were used as exposure chambers. Concentrations of all the chemicals were prepared in acetone. 5, 10, and 15 ppm of Emamectin Benzoate and spinosad were used. Mortality data was recorded after 3, 5 and 7 days while post treatment build up of population was recorded after 35 and 70 days. Results showed that Emamectin benzoate showed more mortality than Spinosad and population build up was less in Emamectin benzoateas compared to spinosad

Biological characteristics, host stage preference and reproductive fitness of mealybug parasitoid *Aenasius bambawalei* Hayat (Hymenoptera: Encyrtidae)

Zain Ulabdin[1], M.Jalal Arif[2], Anjum Suhail[3], M.Ahsan Khan[4], Waqas Wakil[5], M.Dildar Gogi[6], Muhammad Arshad[7], Fiaz Hussain[8]

[1]University of Agriculture, Faisalabad, Pakistan, Pakistan, [2]University of Agriculture, 38040 Faisalabad, Pakistan, Pakistan, [3]University of Agriculture, Faisalabad, Pakistan, Pakistan, [4]University of Agriculture, Faisalabad, Pakistan, Pakistan, [5]University of Agriculture, Faisalabad, Pakistan, Pakistan, [6]University of Agriculture, Faisalabad, Pakistan, Pakistan, [7]University of Agriculture, Faisalabad, Pakistan, Pakistan, [8]University of Agriculture, Faisalabad, Pakistan, Pakistan

Preliminary studies on biological characteristics, host stage preference by a solitary endoparasitoid Aenasius bambawalei Hayat (Hymenoptera: Encyrtidae) and its effects on the reproductive fitness of A. bambawalei were studied on its natural host mealybug, Phenacoccus solenopsis Tinsley (Hemiptera: Pseudococcidae) reared on pumpkin in the laboratory at 28 ±2 oC, 65 ± 5 RH % relative humidity and 18 h light /6 h dark photoperiod. The mean development period of male and female parasitoid was 10.06 and 16.04 days, respectively. The mean development period between oviposition and mummy formation was 6.50 and 7.25 days for male and female, while from mummy formation to adult emergence it was 7.35 and 9.06 days for male and female, respectively. Females started oviposition on the day of emergence and males were short lived (18 days) as compared to females (40 days). A.bambawalei females parasitized 40-180 mealybugs during its life of 10-40 days and accepted mealybugs of all stages but preferred third instar nymphs and adults for oviposition. The sex ratio of resulting parasitoids was close to 1:2. The third instar mealybugs appeared to be the most appropriate hosts for the mass-rearing programme because they gave the best fitness return for the parasitoids. Parasitoid had an excellent searching ability and parasitized the mealy bugs in colonies and the scattered individuals on the plants. Keeping the heavy natural parasitization potential of the parasitoid in view, it is concluded that parasitoid must be conserved and further exploited for biological control of mealybugs.

Genome sequencing and structural characterization of a novel picorna-like virus in a laboratory culture of the endoparasitiod, *Pteromalus puparum* (Hymenoptera: Pteromalidae)

Fei Wang[1], Qi Fang[2], Gong-yin Ye[3]

[1]Zhejiang University, China, [2]Zhejiang University, China, [3]Zhejiang University, China

Pteromalus puparum (Hymenoptera: Pteromalidae) is a dominantly pupal-stage parasitoid wasp of Pieris rapae. It has been verified that P. puparum/P. rapae system is a non-polydnavirus parasitization system, and venom is a key factor which provide protection for the parasitoid eggs against the host immune responses. However, here we reported on the presence of a novel picorna-like virus from P. puparum, designated as PpPRV, according to RNA sequencing and electron microscopy analysis of the parasitoid wasp. Depending on the transcriptomic data assembly and RT-PCR, we got the whole genomic sequence of this single-stranded RNA virus, the sequence represented that PpSRV belonged to picorna-like virus. The full length of the genome of was PpPRV was ~8.9 nt. Only one single open reading frame (ORF) has been found in the positive-sense RNA of PpPRV genome, which encoded two types of proteins. One type were non-structural proteins involving RNA-dependent RNA polymerase and helicase domains, and the other was structural polyprotein containing three conserved picorna-like domains, which were present in the amino and carboxyl-terminus, respectively. Characterization results showed that the genomic structure of PpPRV has high similarity with Marnavirus, another species of picorna-like virus. Although, according to the results of multiple sequences alignment and phylogenetic analysis, we inferred that PpPRV fell into the same clade of phylogenetic tree with a dicstrovirus named black queen cell virus, which contained two independent ORFs in its genome, encoded by positive-sense RNA. The novel discovery of PpPRV is new progress in the research of insect small RNA virus.

The MAP kinase BbSlt2 controls growth, conidiation, cell wall integrity, and virulence in the insect pathogenic fungus *Beauveria bassiana*

Yongjun Zhang
Southwest University, China

Entomopathogenic fungi, such as Beauveria bassiana, are key environmental pathogens of insects that have been exploited for biological control of insect pests. Mitogen-activated protein (MAP) kinases play crucial roles in regulating fungal development, growth, and pathogenicity, mediating responses to the environment. BbSlt2, encoding for an Slt2 family MAPK, was isolated and characterized from B. bassiana. Gene disruption of BbSlt2 affected growth, caused a significant reduction in conidial production and viability, and increased sensitivity to Congo Red and fungal cell wall degrading enzymes. ΔBbSlt2 mutants were altered in cell wall structure and composition, which included temperature dependent chitin accumulation, reductions in conidial and hyphal hydrophobicity, and alterations in cell surface carbohydrate epitopes. The ΔBbSlt2 strain also showed hypersensitivity to heat shock and altered trehalose accumulation, which could only be partially attributed to changes in the expression of trehalase (ntl1). Insect bioassays revealed decreased virulence in the ΔBbSlt2 strain using both topical and intrahemoceol injection assays. These results indicate that BbSlt2 plays an important role in conidiation, viability, cell wall integrity and virulence in B. bassiana.

Baculoviruses - a useful tool for IPM strategies

Philip Kessler
Andermatt Biocontrol AG, Switzerland

Baculoviruses are arthropod specific viruses that usually have narrow host ranges. There is a common consensus that baculoviruses are safe for the environment and human health. Baculoviruses have been predominantly considered to be valuable for biological control in organic farming. Recently the demand increased significantly to include biocontrol products such as baculoviruses also into IPM programmes. In Europe, Cydia pomonella granulovirus (CpGV) has broadly been accepted as a standard in IPM control strategies against codling moth in pomefruit. Far more than 100'000 hectare units of CpGV are applied annually. In Spain, the use of Spodoptera exigua NPV ensures effective control of beet armyworm, without harming beneficial insects. Such integrated control programmes help vegetable growers to produce at low residue levels, a prerequisite for marketing their products through European supermarkets. South African citrus growers successfully include Cryptophlebia leucotreta granulovirus in their control programmes against false codling moth, as export requirements demand low residues. Field trials in France showed that Helicoverpa armigera NPV can be a powerful tool for controlling bollworms in maize. Already one or two applications can effectively control the pest, and therefore the use of the virus offers an additional element for grower's plant protection strategies. The advantages of integrating baculoviruses into IPM strategies are (1) no residues, (2) no hazard for beneficial insects, (3) population control, and (4) resistance management. The key for a broader acceptance will not only be to offer products at competitive prices, but also to provide reliable instructions, appropriate logistics and consistent product quality.

Integrated pest management through sub-lethal synergy between chemical insecticides and entomopathogenic fungi

Justin Louis Hatting[1], Nokulunga Mzimela[2]

[1]Small Grain Institute, South Africa, [2]Small Grain Institute, South Africa

Synergism between chemical insecticides and entomopathogenic fungi (epf) is well documented, an approach seeking to bridge the divide between chemical and biological pest suppression. The premise of this approach, being: two 'materials' assisting each other; the pathogen making the pest sick enough to become less resistant to the chemical and the chemical weakening the pest sufficiently to make it more susceptible to infection. Effective 'two-in-one' tank mixtures can reduce the quantity of insecticide needed (lower residues, costs) while at the same time address the risks of insecticide-induced resistance and environmental contamination. In South Africa, wheat (Triticum aestivum) is prone to infestation by any of six cereal aphid species, notably the Russian wheat aphid, Diuraphis noxia (Kurdjumov). The systematic development of host plant resistance-breaking biotypes of D. noxia implies that wheat producers may have to revert to using chemical insecticides with negative environmental consequences. Compatibility assays were conducted using two species of epf, Beauveria bassiana and Metarhizium anisopliae, with the insecticides Aphox® (pirimicarb), Mospilan® (acetamiprid) and/or Dursban® (chlorpyrifos), measuring percentage conidial germination and radial vegetative growth. Combinations tested were found to be compatible, except for B. bassiana + chlorpyrifos at concentrations ≥25% (of label rate). Comparatively, mortality of D. noxia following treatment with B. bassiana (mean 812±25 conidia/mm2), pirimicarb (1%) and combinations thereof, indicated an added benefit of ca.10% mortality (chemical + fungus), which may have accrued from chemically-stressed aphids being more susceptible to the fungal component in the mixture. Assays with additional combinations were subsequently performed and results are discussed.

Genetic evidence for a role of prophenoloxidase 1 in the *Drosophila* immune response

Olivier Binggeli[1], Mickael Poidevin[2], Bruno Lemaitre[3]

[1]EPFL, Switzerland, [2]CNRS, France, [3]EPFL, Switzerland

Melanization is an invertebrate specific immune reaction that takes place within minutes following infection or wounding. During melanisation, phenols are oxidized into quinones that polymerize to form melanin. This reaction also leads to the production of reactive oxygen species that are thought to be directly toxic to microorganisms. Phenoloxidase (PO) is the key enzyme in this process. This enzyme is synthesized as an inactive zymogen called pro-phenoloxidase (PPO) that is activated by a serine protease cascade. Despite its conservation in many others invertebrates, melanization is one of the less characterized immune reactions in Drosophila. Moreover, some controversy exists on the relevance of the melanization reaction to combat pathogenic infections. To better understand the role of melanization in Drosophila immunity, we recently generated a null mutation in the gene encoding the Drosophila prophenoloxidase 1 (PPO1). To our knowledge, this is the first report of a PPO mutation among Insects. Interestingly, PPO1 mutant flies have a reduced phenoloxidase activity upon septic injury but a wild-type level of Toll and Imd pathway activity. However, PPO1 is required to combat infections with some Gram-positive bacterial species as PPO1 deficient flies show an enhanced susceptibility to Staphylococcus aureus. Surprisingly, PPO1 flies displayed an increased resistance to natural infection with Beauveria bassiana, an entomopathogenic fungus. Altogether our results indicate that PPO1 is an essential component of the antimicrobial response of Drosophila.

The damage efficiency of *Metarhizium anisopliae* and *Beauveria bassiana* on the larvae of coffee white stem borer *Xylotrechus quadripes* (Cherrolat) (Coleoptera: Cerambycidae) under laboratory conditions

Arporn Puntongcum[1], Sa-ngiam Phailom[2], Sopon Uraichuen[3], Kosol Charernsom[4]

[1]National Biological Control Research Center, Thailand, [2]Research and Development of Higher Agriculture, Thailand, [3]National Biological Control Research Center, Thailand, [4]National Biological Control Research Center, Thailand

In Doi Chaang village, Chiang-rai Province, there is a major pest to Arabica coffee called the coffee white stem borer, Xylotrechus quadripes (Cherrolat) (Coleoptera: Cerambycidae). From January 2010 to December 2011, its reactions to Metarhizium anisopliae and Beauveria bassiana were tested under laboratory conditions. Through a completely randomized experimental design we used seven treatments of M. anisopliae and B. bassiana at various concentrations with 106, 107 and 108 spore/ml. and control (water mixed nonionic surfactant) were precisely evaluated. Five of the first insect instar larvae were infested by fungi and each treatment was replicated three times. The preliminary results showed that both fungus with the all concentrations treated at 108, 107 and 106 spore/ml could infect coffee white stem borer up to 100 percent after 4, 6 and 8 days after the infection respectively. M. anisopliae damaged larvae until dead with the appearance of white mycelium covered joints of larvae and then formed hold green spore all over the bodies. Meanwhile, B. bassiana showed only white. This investigation showed that both fungi have high potential to control coffee white stem borer.

Various infection status and molecular evidence for horizontal transmission and recombination of *Wolbachia* and *cardinium* among rice planthoppers and related species

Kai-Jun Zhang[1], Xiao Han[2], Wen-Chao Zhu[3], Xiao-Yue Hong[4]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China, [4]Nanjing Agricultural University, China

Wolbachia and Cardinium are widely distributed and are considered important for their ability to disturb reproduction and affect other ?tness-related traits of their hosts. By using Multilocus Sequence Typing (MLST), RFLP (restriction fragment length polymorphism) and 16S rDNA gene sequencing methods, we extensively surveyed Wolbachia and Cardinium infection status of four predominant rice planthoppers and one kind of leafhopper in different rice fields. The results demonstrated that Sogatella furcifera (Horvath) and Laodelphax striatellus (Fallen) were infected with the same Wolbachia strain (wStri), while Nilaparvata lugens (Stal) and its closely related species Nilaparvata muiri China were infected with two phylogeneticlly distant strains, wLug and wMui, respectively. Three new Wolbachia strains (provisionally named wMfas1, wMfas2 and wMfas3) were detected in the leafhopper Macrosteles fascifrons (Stal). Only S. furcifera was co-infected with Cardinium, which indicated that the distribution of Cardinium in these rice planthoppers was narrower than that of Wolbachia. Unambiguous intragenic recombination events among these Wolbachia strains and incongruent phylogenetic relationships show that the connections between different Wolbachia strains and hosts were more complex than we expected. These results suggest that horizontal transmission and host associated specialization are two factors affecting Wolbachia and Cardinium infections among planthoppers and their related species.

Effects of *Maruca vitrata* multiple nucleopolyhedrovirus on non-target insect pests and natural enemies

Srinivasan Ramasamy[1], Mei-ying Lin[2], Yun-che Hsu[3], Chun-chu Huang[4]

[1]AVRDC-The World Vegetable Center, Taiwan, [2]AVRDC-The World Vegetable Center, Taiwan, [3]AVRDC-The World Vegetable Center, Taiwan, [4]AVRDC-The World Vegetable Center, Taiwan

A nucleopolyhedrovirus (NPV) specifically infecting legume pod borer, Maruca vitrata, was characterized based on ultra-structural morphology, restriction endonuclease cleavage patterns, and sequences of the coding region of the polyhedrin gene, and named as MaviMNPV in Taiwan. This is the first report of a NPV infecting M. vitrata. Laboratory bioassays and field experiments had shown MaviMNPV is highly effective against early larval instars of M. vitrata. Because the newly identified MaviMNPV targeting M. vitrata may affect other insects, it is important to assess its activity against selected non-target insect pests and natural enemies that coexist with M. vitrata in vegetable legume production systems. MaviMNPV was tested at the recommended dose (106 OBs/ml) and a higher dose (107 OBs/ml) against non-target insect pests such as Asian corn borer (Ostrinia furnacalis), tomato fruit worm (Helicoverpa armigera), common armyworm (Spodoptera litura) and beet armyworm (S. exigua), and a generalist predator, green lacewing (Mallada basalis) that occur in vegetable legume production systems in Southeast Asia. MaviMNPV did not kill O. furnacalis, H. armigera, S. litura or S. exigua, nor did it affect larval mortality, larval period, pupal mortality, pupal period, pupal weight, adult emergence, fecundity and egg hatchability. MaviMNPV did not affect the larval survival, pupation and adult emergence of the predator M. basalis when it was fed with virus-infected M. vitrata larvae. We concluded that MaviMNPV did not have any adverse effects on non-target insect pests and predators that coexist with M. vitrata in vegetable legume production systems.

Localization of deformed wing virus (DWV) and Korean sacbrood virus (KSBV) in olfactory organs of honeybees

Ki Bae Hong[1], Je won Jung[2], Hyung wook Kwon[3]

[1]Seoul national University, Republic of Korea, [2]Seoul national University, Republic of Korea, [3]Seoul national University, Republic of Korea

The honeybee is an important economic resource insect for the pollination of many crops, and a unique model to study nervous system processes which shows complicated social behaviors. But viruses are one of the most major threats to the honey bee colony losses around the world and cause serious concerns for beekeepers and researchers. In vertebrates and invertebrates, virus infections affect morphological and functional changes in the nervous system including a wide range of sensory, motor function, and other behaviors. Deformed wing virus (DWV) is a positive-strand RNA virus and detected in many bee colonies, indicating that DWV infection is very abundant and lead to deformation of wings, paralysis and mortality of emerging bees. Honeybee sacbrood virus (SBV) belongs to picornavirus, a small positive strand RNA virus, causing the failure to pupate and death in both larval and adult bees. In this study, we investigated infectious pathways of two viruses into the haemolymph and identified the presence of DWV and SBV viral RNA in several areas involved in olfactory systems in honeybees.

Biological control of *Plutella xylostella* L. and *Aedes aegypti* L. larvae by using *Bacillus thuringiensis* Fusants.

Siti Sumarmi[1], Sebastian Margino[2], Damar Tri Boewono[3], RC. Hidayat Soesilohadi[4], Rina Wahyu Cahyani[5]

[1]Fakultas Biology, University of Gadjah Mada, Indonesia, [2]Fakultas Pertanian, University of Gadjah Mada, Indonesia, [3]BBPVRP Salatiga, Department of Health, Republic Indonesia, Indonesia, [4]Fakultas Biologi, University of Gadjah Mada, Indonesia, [5]Faculty of Biology, University of Gadjah Mada, Indonesia

Pathogenicity of five fusants of Bacillus thuringiensis namely F2, F4, F16, F21 and F36 to P. xylostella and Ae. aegypti larvae were investigated to find an alternative of bio-agent to control both insects. The method used for pathogenicity tests was dip leaf bioassay method, method, and LC50 and LC95 values of five Bt. fusants were analysed by using Probit analysis and Abbot formula to determine LC50 and LC95. The research showed that five strains of Bt. fusants showed specific pathogenic to larvae P. xylostella and Ae. Aegypti. Fusant F16 was the highest pathogen against P. xylostella with LC50 = 3,37 x 1016 cell/ml and LC95 = 2,36x1031 cell/ml at 48 hours after treatment but was not pathogen to Ae. aegypti larvae. Meanwhile, Fusant F36 has the highest pathogenicity to Ae. aegypti for both the second and third instar larvae with LC50 and LC95 values for the second instars larvae were 4,394x105 and 2,423x107 cell/ml at 48 and 72 hours respectively where as it was not pathogen to P. xylostella . the other three fusant strains were not pathogen to both insect. As a conclusion there were no fusants have a double pathogenic against P. xylostella neither Ae. Aegypti.

White grub pathogens and characterization of scarab species in Mauritius and Tanzania

Nirupa Behary Paray[1], Nyembezi Mgocheki[2], Shabani Mmanga[3]

[1]Mauritius Sugar Cane Industry Research Institute, Mauritius, [2]Stellenbosch University, South Africa, [3]TPC Ltd, Tanzania

The present paper focuses on a EU-funded ACP Sugar Research project on the development of biopesticides for the management of white grub species in sugar cane in the Southern African Development Community (SADC) region. The prevalence of indigenous entomopathogens on the scarab species in Mauritius and Tanzania is described. On-going research on pathogen detection revealed the presence of entomopathogenic bacteria, nematodes and fungal pathogens namely Metarhizium anisopliae, Beauveria sp. and Orphiocordyceps sp. on the white grub in Tanzania. Several isolates of the former species, bacteria and nematodes were also detected on white grubs in Mauritius. In addition, Beauveria sp. was identified from soil samples. Investigations into the species composition and population dynamics of white grubs using molecular diagnostic techniques are also described. Accurate species identification is essential to ecological studies and to formulate appropriate pest management strategies. Integrated morphological and molecular studies were necessary to demonstrate the grouping of pleurostict scarabs prevalent in both countries. Two mitochondrial (cox 1 and 16S rRNA) and one nuclear (28S rRNA) gene regions had been used. The phylogenetic tree obtained by the Neigbour Joining method showed high congruence indicating the reliability of the gene regions and primers used. Several species had been identified belonging to three subfamilies of scarabaeidae namely Dynastinae, Melolonthinae and Rutelinae. The results show that DNA barcoding can be used to complement or ascertain morphological identifications. Results from the present work will be used to establish the links between the pathogen and the host insect.

Effects of entomopathogenic fungal endophytes on mortality, oviposition, emergence and longevity of *Liriomyza huidobrensis* (Diptera: Agromyzidae)

Komivi Senyo Akutse[1], Nguya Kalemba Maniania[2], Komi Kouma Mokpokpo Fiaboe[3], Johnnie Van den Berg[4], Sunday Ekesi[5]
[1]ICIPE, Kenya, [2]ICIPE, Kenya, [3]ICIPE, Kenya, [4]North West University, South Africa, [5]ICIPE, Kenya

Liriomyza leafminer flies are exotic pests of economic importance on horticultural crops in Africa and are also treated as quarantine pests in overseas markets. Parasitoids and entomopathogens are among the best control options for this pest. Ten fungal isolates belonging to the genus Beauveria (3), Hypocrea (1), Gibberella (1), Metarhizium (2), Trichoderma (1) and Fusarium (2) were screened for their endophyte properties on Vicia faba and Phaseolus vulgaris. Beauveria (IC279), Hypocrea, Gibberella, Fusarium (M6SF1, M7SF3) and Trichoderma isolates colonized the total host plant of both species. Beauveria isolates G1LU3 and S4SU1 colonized the whole plant of P. vulgaris but only the root and stem in V. faba. Isolates of Metarhizium failed to colonize any of the two host plants. The effects of fungal endophytes on mortality, oviposition, emergence and longevity of L. huidobrensis were tested in planta through colonization of V. faba plants. All the fungal endophyte isolates that succeeded in colonizing the whole or parts of plants were pathogenic to L. huidobrensis causing 100% mortality within 13.2±0.7 and 15±0.6 days. However, the Hypocrea isolate outperformed the other isolates in reducing adult survival (3.8±1.0 days vs. 9.9±1.8 days in the control), number of pupae (80±6.7 vs. 387±21.7 pupae in the control), longevity of the progeny (11.2±1.0 vs. 17.8±1.4 days in fungus-treated and control, respectively) and adult emergences.

Epidemiological studies on tick and mange infestation in camels in Pakistan (Cholistan, Bahawalpur).

Fiaz Muhammad Qamar
Govt. College University, Pakistan

Prevalence of ecto-parasites in camels (Camelus dromedarius) was investigated in Cholistan, Bahawalpur-Pakistan. Ticks (Acari: Ixodidae) are one of the most prevalent ectoparasites in camels that cause acute or chronic illnesses, and can transmit a variety of disease agents to human beings, domesticated animals, and wildlife. Ticks have high reproductive potential, few natural parasites and predators, the ability to live several months or years, and relatively broad host ranges. They are well adapted for survival and difficult to control. In the present study clinical and epidemiological aspects tick and mange infestations of Cholistani camels in Bahawalpur region were reported. A total of 450 camels were examined from 90 herds, 250 animals were found to be infested with ticks and mange infestation from 70 different herds. The overall prevalence of ticks and Mange infestation was 55.55% and 40.80% respectively. The highest district wise prevalence was noted at Rahim Yar Khan (60.87%), followed by Bahawalnagar (49.75%) and the lowest at Bahawalpur (41.05%). The camel ticks on order of their preference were as: Rhipicephalus spp (28.95%) Hyalomma dromedarii (26.48%), Dermacentor sp (18.29%) H. anatolicum (12.47%), H. marginatum (6.69%), Ornithodoros spp. (4.89%) and Amblyomma variegatum (2.20%). Heavy infections lead to decrease in draught capacity, milk production in lactating dams and growth rate in young animals. Chrysomyia spp. and Wohlfahrtia magnifica are the most important myiasis producing flies affecting camel and cause vaginal and preputial myiasis. Cephalopina titilator fly was found to cause nasal myiasis in camel. The tick load per animal was higher during summer.

Effect of Xennorhabdus nematophila on *Microplitis mediator* Haliday

Ziyan Nangong[1], Shan-Shan Feng[2], Ping Song[3], Qin-Ying Wang[4]

[1]Agricultural University of Hebei, China, [2]The government of Xin zhuang ying country of Cixian county, China, [3]Agricultural University of Hebei, China, [4]Agricultural University of Hebei, China

Xenorhabdus nematophila HB310(Xn HB310), an entomopathogenic bacterium appeared high toxic activity against several species of insect including Helicoverpa armigera (cotton bollworm, CBW). We investigated the effects of the culture broth and protein toxin of sublethal concentration on the development of the parasitic wasp of CBW larvae, Microplitis mediator. The results showed that 2.24×106 CFU/mL culture broth and 567.60 μg/mL protein toxin had not direct influence on the pupae emergence of M. mediator. When fed on the 10% honey with the culture broth(? 1.12×105 CFU/mL) or protein toxin (?200μg/mL), the longevities of M. mediator adults were shorten significantly. When the CBW larvae was fed on the diet containing the culture broth (1.12×103CFU/mL) from neonates on, there was no effects on the growth and development of M. mediator in the CBW larvae. Compared with the control, the larval duration of M. mediator was delayed significantly when the host larvae fed on the diet containing 0.38 μg/mL protein toxin from hatch. When CBW larvae fed on the diet with ?IC50 culture broth or protein toxin from parasitized 2nd larvae on, there was no detrimental effect on the development of M. mediator in CBW larvae. The wasp adult would not fed on high dose of Xn HB310 culture broth or protein toxin in natural conditions. These results supported the conclusion that the application of Xn HB310 is safe on the M. mediator.

Bark beetle, *Hypocryphalus mangiferae* Stebbing (Coleoptera: Curculionidae: Scolytinae) is a vector of mango

Shafqat Saeed[1], Assad Masood[2], Yong Jung Kwon[3]

[1]Bahauddin Zakariya University, Pakistan, [2]Bahauddin Zakariya University, Pakistan, [3]Kyungpook National University, Republic of Korea

Role of bark beetle Hypocryphalus mangiferae (Coleoptera: Curculionidae: Scolytinae) was assessed and proved as a definitive vector in the transmission of Mango Sudden Death Syndrome (MSDS). Studies were carried out in the southern Punjab, Pakistan. Healthy plants of mango (Mangifra indica L.) were enclosed with beetles with and without fungus inoculum by employing a technique "Mesh Enclosure Method" (MEM). Symptoms expression revealed that the wilting was significant in 3 and 6 months but no significant differences in oozing were found and also other symptoms like black streaks and cankers were observed in the plants on which infested beetles were introduced. Re-isolation of fungi after 7.5 months showed higher frequency of Lasiodiplodia theobromae compared to Ceratocystis fimbriata. In order to confirm the results, both of the fungi were also isolated from adult beetles and beetle's frass. Based on our findings, H. mangiferae was found to transmit the infection of Mango Sudden Death Disease in healthy plants.

Entomological surveillance on a continental scale: A new application of social networking

Lee William Cohnstaedt[1], Elin Maki[2]

[1]United States Department of Agriculture-Agricultural Reseach Service, U.S.A., [2]United States Department of Agriculture-Agricultural Reseach Service, U.S.A.

Arthropod surveillance is often limited by the short seasonal window of activity, funding, shortage of collection equipment, and the laborious nature of mosquito collection and species level identification; therefore simultaneous sampling of disease vectors on a continental scale has not been achieved in North America. By using social networking to contact and coordinate mosquito collections the Arthropod-Borne Animal Diseases Research Unit, a part of the United States Department of Agriculture, was able to collect 453 mosquito populations of Aedes vexans and Culex tarsalis throughout North America during the summer of 2011. Mosquito abatement districts, health departments, and individuals (530 total) were contacted by email (320), phone call (142), face-to-face (58), or by another method (10). These contacts demonstrated the value of social networks by recruiting an additional 202 people, a 38% increase. However, the importance of personal contact cannot be understated. Although "face-to-face" contacts represented only 8% of the total contacts, they provided 23% of the mosquito populations. Methods for finding, contacting, coordinating, and motivating contacts will be discussed in the presentation. Mosquitoes and the diseases they transmit are not limited by geo-political boundaries, therefore in the future social networking may increase coordination and effectiveness of mosquito abatement projects across the target species' entire geographic distribution.

Mosquito monitoring program at Honolulu International Airport, Hawaii

Jeomhee Mun Hasty[1], Ping Yang[2], Peter Oshiro[3], Lynn Nakasone[4], Gary Gill[5]

[1]Hawaii, U.S.A., [2]Hawaii, U.S.A., [3]Hawaii, U.S.A., [4]Hawaii, U.S.A., [5]Hawaii, U.S.A.

A mosquito surveillance program using Ovi-traps has been in continuous operation at the Honolulu International Airport for 2 years (May 2010 to April 2012). To the best of our knowledge, this is the first use of routine Ovi-trap monitoring at that site. Previous to this project, gravid and light traps were standardized components of public health mosquito surveillance at the airport. That effort was terminated in 2009. The current program focuses on (1) monitoring for the long-established day-time mosquito Aedes albopictus and (2) surveying for the introduction of mosquito species new to Oahu or the state. A. albopictus egg counts have fluctuated over time during the surveillance program. Preliminarily, we can say that oviposition at this site increases throughout the rainy season (October ? April). Most of this seasonal increase in mosquito oviposition occurs in the 2nd ? 3rd months of the rainy season, when heavy rains peak and then decline. Oviposition decreases within one month of consistent declines in rainfall at the end of the rainy season. Inter-annual variations within this generalized pattern are evident. In January 2012, A. aegypti was detected from a small garden located between terminals for out-of-state and within-state flights. This species had not been confirmed present on Oahu since 1949. This recent finding of A. aegypti has led us to intensify our surveillance program at the airport, with the hope that we will improve our understanding of the nature of mosquito introductions at this important port of entry for the Hawaiian islands.

Culex molestus and implications for mosquito-borne disease risk in Australia.

Nur Faeza Abu Kassim[1], Cameron E. Webb[2], Richard C. Russell[3]

[1]The University of Sydney, Australia, Australia, [2]The University of Sydney, Australia, [3]The University of Sydney, Australia

The Culex pipiens subgroup of mosquitoes includes important species involved in mosquito-borne disease transmission internationally and four species within this subgroup are found in Australia. One of these species, Culex molestus, is thought to have been introduced into Australia in the 1940s but its importance as a vector of mosquito-borne viruses is not well understood and there is some debate regarding the relationship between this species and others in the Culex pipiens subgroup. Laboratory studies have shown that the species is uniquely adapted to subterranean habitats and the current trend towards increased water storage in urban areas has raised concerns of increased nuisance-biting and public health risks in the future. Concern has been raised as to the potential role this species may play in the transmission of exotic arboviruses such as West Nile virus and locally important arboviruses such as Murray Valley encephalitis virus. However, notwithstanding the vectorial capacity of this species, there may be ecological barriers that diminish the public health risks associated this species. This paper will present the findings of biological, ecological and molecular studies of Culex molestus with implications for the assessment of mosquito-borne disease risk.

Aedes aegypti productivity and fecal contamination in domestic water storage containers in two villages in Northeastern Thailand

Nsa Dada[1], Nanthasane Vannavong[2], Razak Seidu[3], Audrey Lenhart[4], Thor-Axel Stenstrom[5], Theeraphap Chareonviriyaphap[6], Hans Jørgen Overgaard[7]

[1]Norwegian University of Life Sciences, Norway, [2]Norwegian University of Life Sciences, Norway, [3]Norwegian University of Life Sciences, Norway, [4]Liverpool School of Tropical Medicine, United Kingdom, [5]Norwegian University of Life Sciences, Norway, [6]Kasetsart University, Thailand, [7]Norwegian University of Life Sciences, Norway

Little is known about the relationship between Aedes aegypti production and fecal contamination in domestic water storage containers. To investigate this relationship, we conducted a cross sectional survey in NE Thailand in 122 and 128 houses in one rural and one suburban village, respectively. Overall, Ae. aegypti container, house and Breteau indices (18.9, 73.6 and 140) were above the WHO transmission thresholds for yellow fever, which are also applied to dengue, with a significantly higher container index in the suburban village ($p<0.05$). Overall pupae per person and pupae per house were 2.4 and 8.2 respectively, with no significant difference between villages. Seventy one percent of Ae. aegypti infested containers were positive for Escherichia coli, a commonly used indicator of fecal contamination and diarrheal disease risk, with the odds of E. coli contaminated containers being infested with Ae. aegypti ranging from 3.8 in the rural village to 5.7 in the suburban village. Ae. aegypti productivity was significantly higher in domestic containers co-infested with E. coli than in containers infested with only Ae. aegypti ($p<0.01$). Similarly, significantly higher levels of E. coli contamination were detected in containers infested with Ae. aegypti ($p<0.01$). The evident relationship between Ae. aegypti productivity and fecal contamination suggests that domestic containers in these settings are potentially important determinants of dengue and diarrheal disease. These containers could be excellent targets for combined control of both diseases. In further research, we will explore how this relationship can be targeted to develop integrated dengue and diarrheal disease control strategies.

African Horse Sickness, its *Culicoides* (Diptera, Ceratopogonidae) vector and Hartmann's mountain zebra in the south-west Khomas Region, central Namibia.

Huibrecht Van Hamburg[1], Elbe Becker[2]

[1]*North-West University, South Africa,* [2]*North-West University, South Africa*

African Horse Sickness (AHS) is considered endemic to Namibia. Four of the nine known AHS virus serotypes (AHSV 1, 2, 4 and 9) were recently isolated from horses around the Windhoek area. Farmers have reported several horse casualties in the south-western Khomas Region, which was unexpected, as the area is particularly dry ? conditions thought unfavorable for the vector of African Horse Sickness Virus, namely Culicoides midges. The objective of this study was to determine the presence of factors necessary for the maintenance of AHS in the Khomas Region of Namibia, namely the Culicoides vector and a suspected African Horse Sickness Virus reservoir host or source, the Hartmann's mountain zebra. The distribution and abundance of Culicoides species was determined and an unexpected high diversity of species was found even during winter months. Hartmann's mountain zebras were found in significant numbers along the survey transect. ELISA tests of blood samples taken showed a 100% presence of AHSV antibodies in all the samples, indicating the survival of the zebras after exposure to the virus. This study indicated the importance of human settlement in the Khomas Region on the Culicoides distribution by investigating the background Culicoides populations away from homesteads. Further research is identified to determine the importance of the Khomas Region as an endemic source of African Horse Sickness Virus in the region.

Survey of some bionomic factors of *Culex tritaeniorhynchus* (Diptera: Culicidae) as vector of Japanese Encephalitis (Brain fever)

Mohammad Reza Fakoorziba[1], Fariba Eghbal[2], V.A. Vijayan[3]

[1]School Of Health and Nutrition, Shiraz University of Medical sciences, Iran, [2]School of Medicine, Kazerun Branch, Islamic Azad University, Iran, [3]University of Mysore, India

Background: Diseases transmitted by arthropods are among the major causes of illness and death in many tropical and subtropical countries. Among these communicable diseases, Japanese encephalitis is endemic in at least 21 countries. Rapidly changing environment brings about frequent changes in vector behavior, which necessitate the regular general information on vector bionomics, so the present study undertaken to identify some ecological parameters that affect on vector of JE. Material and Methods: Mysore city of Karnataka state, India were selected for the present study mainly because of the endemicity of JE and prevalence of Cx. tritaeniorhynchus, the major vector of JE. The larvae of Cx. tritaeniorhynchus and associated species have been collected from temporary and semi permanent ground water pools. Simultaneously they have also been collected from plain rice field area from a 26 km radius outside Mysore. For the present study all the abiotic factors and one biotic factor estimated were subjected to statistical analysis to determine whether these could influence the larval density of Cx. tritaeniorhynchus. Results and Discussion: In the base of standardised coefficients Beta the most effective variables (predictor) on larval density among the 3 variables such as pH, height of paddy and density of Cx. fuscanus are height of paddy and pH. These results relating to some aspect of ecology of Cx. tritaeniorhynchus will help us to manage this species as well as assess the effects of human activities including land use pattern that could create epidemics of brain Fever and other mosquitoes borne diseases.

The leishmaniasis are estimated to affect 10-50 million people in the world. Visceral leishmaniasis (VI) caused by leishmania infantum, is endemic in several parts of world especially in Mediterranean regions. This disease is endemic in southern and north- west area in Iran. This disease without diagnosis and treatment can lead to death. We need epidemiological study including demographical factor, vectors, reservoirs and agents for the best way to control and prevention of this sandfly borne diseases. In this regard for the first phase of this investigation the files of 141 cases were studied with diagnosis of VI in Namazi hospital of Shiraz (Iran) during 2006-2011. Results showed that 54% of patients were boys and 46% were girls. The peak incidence of VI observed in winter (35.46%) followed by spring, summer and autumn respectively. Mortality was reported 9.20% in this study and 9.12% of patients developed relapse of disease. More patients were from rural areas. The species of Phlebotomus sandflies that were investigated as vectors of VI in Iran are: ph.major, ph. keshishiani, ph. kandelaki, ph. alexandri and ph. perfiliewi. The results of this research are useful for control of VI in this endemic area of disease in Iran.

Goat hoof myiasis caused by *Wohlfahrtia magnifica* (Diptera: Sarcophagidae) larva in Dashte-arjan region, Fars, Iran

Hamzeh Alipour[1], Masoud Neghab[2]

[1]*School of Health and Nutrition, Shiraz University of Medical Sciences, Iran,* [2]*Shiraz University of Medical Sciences, Iran*

Introduction and Objectives: Myiasis, is the infestation of tissues and organs of living vertebrate animals and humans by larval stages of Diptera. It is a world-wide problem, particularly, in tropical regions and a cause of severe financial losses. Although it is more prevalent in animals, it is also a relatively frequent occurrence in humans in rural areas. The main purpose of this study was to identify and characterize the flies responsible for goat hoof myiasis in Dashte-arjan region of Fars province in Iran. Materials and Methods: The Larvae were removed from the hooves, manually. Thereafter, they were identified by light microscopy on important morphological characteristics such as posterior spiracles and pictorial key. Results and Conclusions: Wohlfahrtia magnifica was isolated from goats' hooves. About 5% of the examined goats had larvae-infested wounds. Cases of myiasis were presented in July. The severity of infections ranged from 5 to 8 larvae in each wound. The case presented is the first case of Wohlfahrtia-induced myiasis in goat hoof in Fars province and indicates that the condition is endemic in the region.

Ecology of malaria vectors in southern part of Iran.

Abdolreza Rajaeifaed[1], Mahmood Reza Nikbakhtzadeh[2], Hamzeh Alipour[3]

[1]Shiraz University of Medical Sciences, Iran, [2]Tarbiat Modares University, Iran, [3]Shiraz University of Medical Sciences, Iran

Malaria is an unstable (stability index<0.5) and mesoendemic disease in Iran. National Malaria Control Program reported 13,821 malaria cases in 2004 of which 45% were imported. Subsequently, a total of 18875 cases were nationally reported in 2005. There appears to be no report on the epidemiological aspects of human malaria in the rapidly growing energy centre, Assalouyeh,. Assalouyeh petrochemical zone in the northern coast of the Persian Gulf is one of the main malaria foci of Iran. It is situated in the Indo- Persian subcontinental epidemiological zone of malaria (Onori et al, 1993), which is a very fast growing field of oil and natural gas. The large influx of international job seekers, as well as the internal immigrants to this centre (>30,000 annually), the presence of capable vectors, ecological instability due to the high rate of human movement and the fragile infrastructure of the local health system are among the main reasons of malaria expansion in recent years. Following an outbreak of malaria in 2002, this research was undertaken in Assalouyeh for the first time to find out the local prevailing circumstances, detect the eco- epidemiologic parameters and response rate of the main malaria vectors to the current control measures.

Toxin peptide produced by *Xenorhabdus* species with a novel mode of action against yellow fever mosquito larvae, *Aedes aegypti*

Il Hwan Kim[1], Jerald Ensign[2], Que Lan[3]

[1]*University of Wisconsin-Madison, U.S.A.,* [2]*University of Wisconsin-Madison, U.S.A.,* [3]*University of Wisconsin-Madison, U.S.A.*

The goal of this study is to examine the toxicity and mode of action of a lipopeptide against larvae of Aedes aegypti, the yellow fever mosquito. Preliminary studies suggested that Xenorhabdus sp. produces small molecular weight peptides that are highly toxic yet specific to larvae of different mosquito species, including Aedes aegypti, Culex pipiens, and Anopheles gambiae. Further studies have been conducted to understand how the toxin peptides affect mosquito larvae. The results from this study indicated that the toxin peptide from Xenorhabdus sp. has acute toxicity against mosquito larvae at very low concentration with different mode of action from Bacillus thuringiensis israelensis toxin (Bti). Based on the cell assays, it was apparent that the toxin peptide is very specific toward mosquito cells, which indicated promising characteristics to be developed as next generation bio-pesticide.

Potent repellents for control of savannah tsetse (*Glossina* sp.)

Rajindar Saini[1], Norber Mbahin[2], Hippolyte Affognon[3], John Andoke[4], Peter Muasa[5], Tiberius Marete[6], David Mbuvi[7], John Ngiela[8]

[1]International Centre for Insect Physiology and Ecology (ICIPE), Kenya, [2]International Centre for Insect Physiology and Ecology (ICIPE), Kenya, [3]International Centre for Insect Physiology and Ecology (ICIPE), Kenya, [4]International Centre for Insect Physiology and Ecology (ICIPE), Kenya, [5]International Centre for Insect Physiology and Ecology (ICIPE), Kenya, [6]International Centre for Insect Physiology and Ecology (ICIPE), Kenya, [7]International Centre for Insect Physiology and Ecology (ICIPE), Kenya, [8]International Centre for Insect Physiology and Ecology (ICIPE), Kenya

Repellents for the control/management of disease vectors like tsetse have been identified at icipe from synthetic sources and from natural blends of un-preferred animals (e.g. waterbuck), which are common in tsetse habitats but not fed upon. The synthetic tsetse repellent 2-methoxy-4-methylphenol (icipe patent) and the 5-constituent waterbuck repellent blend (icipe patent) are being validated in large-scale field trials. A major constraint of the technology however is the dispensing of the repellents on the host. At the moment the repellent collar prototype, breaks easily and needs to be commercially produced. New dispensers (though still not optimal) have been developed and are currently being tested in field trials. The performance of the two repellents in field experiments and their potential in tsetse management will be highlighted. Despite the prototype nature of the technology, our results indicate that these repellents provide substantial protection to cattle either in 'push' mode or when used in conjunction with baited traps in 'push-pull' strategy. Most livestock keepers prefer the repellent technology compared to other tsetse and trypanosomosis control options due to the technology's simplicity and mobility. Investigations of feeding preferences of other vectors may similarly yield useful tools and tactics for their control.

The use of entomopathogenic fungi in the control of tsetse flies

Jean Nguya K. Maniania[1], Sunday Ekesi[2]

[1]International Centre for Insect Physiology and Ecology (ICIPE), Kenya, [2]International Centre for Insect Physiology and Ecology (ICIPE), Kenya

Tsetse flies are vectors of trypanosomes, which cause African trypanosomosis or sleeping sickness in humans and "nagana" in animals. About one-third of the continent, or nearly 9 million km2 is infested; thus, preventing full utilization of the best agricultural/grazing lands on the continent. Due to the lack of vaccines, inexpensive drugs and the development of resistance to drugs by the trypanosomes, vector control remains the only viable option for management of these diseases. The use of insect pathogens that occur naturally in insect populations represents one of the alternatives; but their potential as biological control agents has not been fully exploited, especially due to the difficulty of their application in the field because of the haematophagous behavior of tsetse flies. Since entomopathogenic fungi (EPF) infect their target organisms through the cuticle, as opposed to other pathogens that need to be ingested, it has been possible to develop a device that delivers and autodisseminate inoculum among tsetse in the field. The potential of this technique was tested in the field and results showed a reduction of tsetse population comparable to the conventional mass trapping technology. However, the success of this technology depends on the effective horizontal transmission of the inoculum between insects. We highlight the prospects of using EPF in combination with other technologies for the control of tsetse flies and the challenges related to the application of the technology.

Cost efficient control of tsetse flies

Johan Esterhuizen
Liverpool School of Tropical Medicine, United Kingdom

Tsetse flies (Diptera: Glossinidae) are the vectors of human and animal trypanosomiasis (also called Sleeping Sickness in humans and Nagana in animals). These diseases affect more than 36 countries in sub-Saharan Africa. Research and control of the disease has been ongoing since the early 1900's, yet trypanosomiasis is still responsible for economic losses estimated at US$4.5 billion per year, with a human DALY index of 1.59 million. Disease control is based on breaking the parasite lifecycle with drugs, or targeting the vector to interrupt transmission. For economic and sustainability reasons, vector control is a preferred option, but the ecology and biology of tsetse flies limits the techniques that can be used. For example, savannah tsetse species can successfully be eliminated from a 10 000km2 area for US$ 1million, with insecticide-treated targets. To achieve the same for riverine tsetse species (the major vectors of human trypanosomiasis) with standard methods, would cost US$ 7.5 million, due to dense habitat and poor response of riverine tsetse to current control devices. This presentation reports on a new, significantly cheaper insecticide-treated target for control of riverine tsetse flies. In an ongoing island trial against Glossina f. fuscipes, a population reduction of 99% was achieved within five months. Currently this technology is being evaluated in a large 500km2 trial in north-western Uganda, a foci for human trypanosomiasis. This is the first major advance in control of riverine tsetse species in almost three decades, and provides a crucial tool for management of this neglected tropical disease.

New tools for addressing insecticide resistance in malaria vectors

Tessa B. Knox[1], Elijah Juma[2], Helen Pates Jamet[3]

[1]Vestergaard Frandsen, Kenya, [2]Vestergaard Frandsen, Kenya, [3]Vestergaard Frandsen, Switzerland

The emerging and rapid spread of insecticide resistance threatens the utility of valuable interventions such as long lasting insecticidal nets (LLINs) and indoor spraying of residual insecticides. To inform the optimal deployment of existing insecticide-based tools as well as the development of the next generation of tools, an online interactive platform was created to map reports of insecticide resistance since the 1950s (www.irmapper.com). Data from WHO susceptibility tests are selected by mosquito species, insecticide type and mosquito collection period to produce tailored maps showing key information. Data on target site and metabolic resistance mechanisms are similarly displayed. Information was used to select sites in Uganda(4), Democratic Republic of Congo(3) and Ethiopia(4) for bioefficacy evaluations of WHO-recommended LLINs. Standard LLINs and a combination LLIN were assessed via cone bioassays using local pyrethroid-resistant Anopheles gambiae. Significant reductions in susceptibility to standard LLINs were observed across all 11 sites depending on net type, with minimum mean mortalities of 46-61% for Uganda, 41-52% for DRC and 15-34% for Ethiopia populations. Conversely, the combination LLIN performed well at sites in Uganda and DRC (mean mortality of ≥95%) with reduced efficacy observed for the insecticide-only sides but not the synergist plus insecticide roof for Ethiopia (≥40% and 100%, respectively). Reductions in efficacy of standard LLINs is of particular concern considering all nets tested were new, unused and adhered to target dose ranges. Such data from multiple mosquito populations and tools provides a good basis for informing control decisions in the absence of more comprehensive comparative data.

Implications of larval density-dependence processes on malaria vector control strategies in Kenya

Simon Muriu[1], Tim Coulson[2], Charles Mbogo[3], Charles Godfray[4]

[1]Kenya Medical Research Institute (KEMRI)-Wellcome Trust Programme, Kenya, [2]Imperial College at Silwood Park, United Kingdom, [3]Kenya Medical Research Institute (KEMRI) - Centre for Geographic Medicine Research, Coast, Kenya, [4]University of Oxford, United Kingdom

Back ground: Malaria vector management is an integral part of malaria control strategies in Sub-Saharan Africa. For any successful planning and implementation of vector control strategy prior understanding of the vector bionomics is crucial in order to design and optimize control measures based on when, where and how malaria vectors should managed. Objective: In the current study, density?dependent processes during larval stages in Anopheles gambiae s.s larval habitats and their contribution to population regulation were evaluated. Methodology: A series of experiments were done in which An. gambiae s.s densities and cohort structure were manipulated in the field in Kilifi, Coastal Kenya using artificial habitats set in semi-field conditions. Results: Simple general linear models analysis showed considerable variation in mosquito survival rates, measured by the probability of successful pupation across different densities with 23-31% of the differences in the survival being attributed to mosquito density. The form of the density-dependence was nearly linear when the log-odds of survival were plotted against log density and a two-fold increase in density resulted in a reduction of the log-odds of survival. Higher larval density not only increases mortality but lengthens the time the mosquito requires to reach the pupal stage by 3-4 days. Mosquitoes emerging from high density breeding sites tend to be smaller and consequently have reduced survival rate and fitness. Conclusion: In conclusion strong density-dependence pervades in mosquito larval populations through larval competition with implications on the approaches employed in the control of malaria vectors in natural settings.

Evaluating the potential of the sterile insect technique for malaria control: Relative fitness and mating compatibility between laboratory colonized and a wild population of *Anopheles arabiensis*

Givemore Munhenga[1], Givemore Munhenga[2]

[1]*University of Witwatersrand, South Africa,* [2]*University of Witwatersrand, South Africa*

Background: Successful suppression of a target insect population using the sterile insect technique (SIT) partly depends on the premise that laboratory insects used for mass rearing are genetically compatible with the target population, that mating competitiveness of laboratory reared males is at least comparable to that of their wild counterparts, and that mass rearing and sterilization processes do not in themselves compromise male fitness to a degree that precludes them from successfully competing for mates in the wild. This study investigated the fitness and sexual cross-compatibility between samples of field collected and laboratory reared An. arabiensis under laboratory conditions. Results: The physiological and reproductive fitness of the MALPAN laboratory strain is not substantially modified with respect to the field population at Malahlapanga. Further, a high degree of mating compatibility between MALPAN and the Malahlapanga population was established based on cross-mating experiments. Lastly, the morphological characteristics of hybrid ovarian polytene chromosomes further support the contention that the MALPAN laboratory colony and the An. arabiensis population at Malahlapanga are genetically homogenous and therefore compatible. Conclusions: It is concluded that presence of a perennial and isolated population of An. arabiensis at Malahlapanga presents a unique opportunity for assessing the feasibility of SIT as a malaria vector control option. The MALPAN laboratory colony retained sufficient enough measures of reproductive and physiological fitness to present as a suitable candidate for male sterilization, mass rearing and subsequent mass release of sterile males at Malahlapanga in order to further assess feasibility of SIT in a field setting.

Cow dung, medicinal plants and intermittent irrigation strategy for anopheles mosquito management in Ahero rice paddies

Elizabeth Dorothy Kokwaro[1], Michael Gicheru[2], Michael Kahato[3], Dalmas Ogingo[4]

[1]Kenyatta university, Kenya, [2]Kenyatta university, Department of Zoological Sciences, Kenya, [3]Kenyatta university, Department of Zoological Sciences, Kenya, [4]Kenyatta university, Department of Zoological Sciences, Kenya

Human health is a major concern in many parts of the world. Although irrigated farming has been used to increase food production, this has aggravated the problem of mosquito vectors and subsequent increases in malaria transmission. Integrated vector management targeting both the adult and immature stages has been adopted with renewed interest in larval management with the aim of making it more effective. Targeting mosquito larval habitats like irrigated rice agro-ecosystems of Ahero calls for research to evaluate affordable, environmentally friendly approaches such as cattle dung, intermittent irrigation and neem (Azardirachta indica). This research investigated the effect of cow dung, neem, and intermittent irrigation on immature stages of anopheles mosquitoes. Laboratory and field experiments were carried out in Ahero under different irrigation regimes on malaria vector. Field experiments were designed using a mixed model approach with three treatments replicated four times per block. The highest mosquito larval densities were recorded in Ammonium sulphate treated sub-plots. Results for laboratory experiments indicated that cow dung and neem individually caused significant mortality of immature stages of mosquitoes. A combination of cow dung and neem caused higher mortality than cow dung, neem alone but the difference was not significant. A reduction in the number of larvae in experimental plots with cow dung and neem was recorded suggesting that larvae and adult mosquitoes may be reduced by cow dung and neem. Intermittent irrigation, where draining of the rice paddies was associated with the lowest mosquito larvae could be adopted in mosquito management.

Performace of new products against *Aedes aegypti/albopictus* under laboratory and field conditions: A preparatory approach following the 2011 dengue epedemic in Pakistan

Waseem Akram[1], Ijaz Qureshi[2], Hafiz Azhar Ali Khan[3], Mirza Jawwad Hassan[4], Rizwan Ahmad[5]

[1]Chief Minister's Secretariat, Pakistan, [2]Institute for Public Health, Pakistan, [3]BZ University, Multan, Pakistan, [4]University of Agriculture, Pakistan, [5]University of Agriculture, Pakistan

Pakistan in particular Lahore faced one of the biggest epidemic of dengue ever reported in the world. Vector breeding and the future threats of the disease outbreak alongwith studies on latest products with more environmental friendly impacts were explored. The trials have revealed effectiveness of the products to kill the mosquito populations with minimal impact on the environment. A total of five products containing three Bti formulations one IGR and a physical barrier were tested and a comparison in terms of their performance against all the life stages were reocrded. The results with Aquatain AMF a silicone based polymer (Polydimethylesiloxane PDMS) reveal that the product when used against Aedes aegypti provided 100% mortality of the pupal and 4th instar larvae and 85% mortailty of 3rd after 12 hours of application. 30% mortality was recorded in 1st and 2nd instars, however 90% mortality was recorded in these larvae when they grew up to 3rd and 4th instars. Percent mortality with respect to time in Culex populations were different from the Aedes. Similarly mortality from TMOF-Bti, Mosquito Dunks, Sumilarv (IGR) and MOSTAB-Bti have revealed higher percentages. The performance of Bti products was effected at lower temperatures, but genarlly all of the products performed well at temperatures above 20ºC.

Role of public participation and interventions in dengue management

Waseem Akram[1], Jong Jin Lee[2], Hafiz Azhar Ali Khan[3]

[1]Chief Minister's Secretariat, Pakistan, [2]Chonbuk National University, Republic of Korea, [3]Bahaudin Zakria University, Multan, Pakistan

Abstract: Dengue and the dengue hemorrhagic fever are caused by two known species of mosquitoes Aedes aegypti and Aedes albopictus that have extended their ranges from Asian region to other continents through trade and transportation. Both the species have the capacity to vector all the four serotypes (DEN1, DEN2, DEN3 and DEN4) and ultimately transfer the virus to the people after extrinsic incubation period of 4-6 days. At present Pakistan in particular Punjab stands as the target site for dengue. Climatic changes, unplanned urbanization and the growing environmental concerns may further lead to the expansion of vector's ranges and finally the prevalence of the disease. Places which have shown sever epidemics have also opened doors to other vector borne issues and the continuous application of insecticides may select the resistant forms already reported from Multan, Faisalabad and Lahore to other parts of the Punjab and the country. It is an established fact that not only the interventions and research can prevent the disease outbreak but it is the public participation activated through communication and change in behavior (COMBI) which can make the difference. This paper therefore, highlights the areas of our future strategies for combating with any of the vector borne issues. It emphasizes on the concept that there are multiple options available for the management of vector and if all the components are followed an outbreak can ultimately be prevented.

Repellency of cassia bark, Eucalyptus and Star anise oils and their major constituents to *Leptotomobidium pallidum* (Acari: Trombiculidae)

Kyu Sik Chang[1], E. Hyun Shin[2], Mi Yeoun Park[3], Bong Gu Song[4], Dong-Kyu Lee[5], Young Joon Ahn[6]

[1]Korea Center for Disease Control & Prevention, Republic of Korea, [2]Korea Center for Disease Control & Prevention, Republic of Korea, [3]Korea Center for Disease Control & Prevention, Republic of Korea, [4]Korea Center for Disease Control & Prevention, Republic of Korea, [5]Kosin University, Republic of Korea, [6]Seoul National University, Republic of Korea

Repellents can be effective tools for protecting individuals from mite bites and mite-borne diseases because the mite larvae live in micro spots called mite-islands and control of the chigger mites with residual spray is very difficult. The most widely used repellent products are currently based on N,N-diethyl-3-methylbenzamide (Deet). It is estimated that approximately one-third of the people in the United States use Deet-containing products in various formulations. However, occasional toxic effects of Deet have been reported that include central nervous system depression, urticaria, contact dermatitis, or potential encephalopathic toxicity. There is, therefore, a critical need for the development of more effective new repellents and repellent formulations. An assessment is made of the repellency of cassia bark, eucalyptus and star anise oils and their major constituents against Leptotrombidium pallidum larvae. Results were compared with those of conventional repellents DEET, IR3535 and permethrin. Based on RC50 values, cassia bark oil was the most effective repellent and was 2.5, 12.6 and 15.0 times more effective than Deet, IR3535 and permethrin respectively. Star anise oil was more pronounced in the repellency than eucalyptus oil. The repellency of star anise oil, eucalyptus oil and Deet did not differ significantly from each other. Star anise and eucalyptus oils were significantly more effective than either IR3535 or permethrin. In the light of global efforts to reduce the level of highly toxic synthetic repellents, the three essential oils and their major constituents described herein merit further study as potential repellents for the control of house dust mite populations.

Histopathological effects of pellitorine on larval midgut epithelium and anal gills toward *Aedes aegypti* (Diptera:Culicidae)

Haribalan Perumalsamy[1], Jun-Ran Kim[2], Young-Joon Ahn[3]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Seoul National University, Republic of Korea

The histopathological effects of pellitorine on larval segments of third instars of Aedes aegypti were examined by transmission electron microscopy. Results were compared with those of deltamethrin. At a concentration of 5 mg/L, pellitorine was targeted mainly on midgut epithelium and anal gills, indicating variably dramatic degenerative response of the midgut through a sequential epithelial disorganization. The anterior midgut was almost entirely necrosed, bearing only residues inside the plasma membranes on the basal lamina. The compound has shown complete damage of all glandular cells of anal gills, because cuticle damage was occurred by pellitorine. The histopathological effects 2.5 mg/L of deltamethrin on the different regions of the midgut clearly indicate the epithelial disorganization and delocalization of cell organelles which have been correlated with their morphofunctional status. Based on these results, pellitorine merit further study as a potential larvicide with a specific target site and mode of delivery or a lead molecule for the control mosquito populations.

Insecticide resistance in dengue and malaria vectors and consequences for vector control

Vincent Corbel[1], Sebastien Marcombe[2], Jean Philippe David[3], Fabrice Chandre[4], Andre Yebakima[5], Hilary Ranson[6]

[1]Institut de Recherche pour le Developpement, Benin, [2]Center for Vector Biology, Rutgers University, New Brunswick, NJ 08901, USA, U.S.A., [3]Laboratoire d'Ecologie Alpine (LECA), France, [4]Institut de recherche pour le Developpement (IRD), France, [5]Centre de Demoustication, Conseil General de la Martinique, France, [6]Vector Group, Liverpool School of Tropical Medicine, United Kingdom

The use of insecticides in public health has increased dramatically in the past decade through the scale up of insecticide treated net distribution programmes, indoor residual spraying and larviciding campaigns or space spray operations. Inevitably, the major malaria and dengue vectors have developed resistance to these insecticides and the resistance alleles are now spreading at an exceptionally rapid rate worldwide. Although decades of extensive research and substantial progress have been made on understanding the causes of insecticide resistance, remarkably few studies have focused on the impact of resistance on current vector control activities. Here, we will address the current distribution of insecticide resistance in dengue and malaria vectors in the tropics and discuss its implications for vector control in different settings (South East Asia, Africa and Caribbean). The evidence that insecticide resistance represents a major threat for the control of dengue and malaria calls for new vector control strategies in the coming years

Sumilarv®0.5G, Promising insecticide for the control of *Anopheles gambiae*

Oscar Ochieng Mbare[1], Ulrike Fillinger[2], Steve Lindsay[3]

[1]London School of Hygiene and Tropical Medicine, Kenya, [2]London School of Hygiene and Tropical Medicine, Kenya, [3]London School of Hygiene and Tropical Medicine, Kenya

Malaria vector control with long-lasting insecticidal nets (LLINs) and indoor residual spraying (IRS) has resulted in a significant decline of malaria in Africa. However, recent reports have shown both behavioural avoidance and physiological resistance to insecticides by vectors. Thus, the need to explore and integrate other tools for malaria vector control. Larval source management is a proven tool for control. Difficulties with larviciding are (1) interventions are based at targeting all aquatic habitats and (2) current larvicides have short residual activity requiring weekly application which necessitate large labour and large amounts of larvicides is not cost effective especially in Africa. Thus the need to evaluate persistent larvicides and study sound application strategies. Sumilarv is a persistent larvicides that with great potential for mosquito control. Bioassays showed that Sumilarv was ten times more effective that microbials for Anopheles control. Sumilarv application at 0.05 ppm a.i resulted in 80% emergence inhibition for upto 6 weeks in standardized field conditions. Evaluations of the optimum dose of Sumilarv identified in the standardized field tests are on-going in an area of focal malaria transmission in Western Kenya. Preliminary results from the first three months of field testing indicate the three week application results on average in 71% emergence inhibition of malaria vectors from treated sites. The use of residual larvicides has a risk of vector production from untreated habitats created or filled with water after larvicide application. Intensive monitoring and sampling of sites is ongoing to estimate this risk in the dry and rainy seasons.

Scientists and public involvement: A consultation on the relation between malaria, vector control and transgenic mosquitoes

Christophe Boete
IRD - Aix Marseille University, France

Among the hopes for vector-based malaria control, the use of transgenic mosquitoes able to kill malaria parasites is seen as a potential way to interrupt malaria transmission. While this potential solution is gaining some support, the ethical and social aspects related to this high-tech method remain largely unexplored and underestimated. Related to those latter points, the aim of the present survey is to determine how scientists working on malaria and its vector mosquitoes perceive public opinion and how they evaluate public consultations on their research. This study has been performed through a questionnaire addressing questions related to the type of research, the location, the nationality and the perception of the public involvement by scientists. The results suggest that even if malaria researchers agree to interact with a non-scientific audience, they (especially the ones from the global North) remain quite reluctant to have their research project submitted in a jargon-free version to the evaluation and the prior-agreement by a group of non-specialists. The study, by interrogating the links between the scientific community and the public from the perspective of the scientists, reveals the importance of fostering structures and processes that could lead to a better involvement of a non specialist public in the actual debates linking scientific, technological and public health issues in Africa.

Technical basis for deployment of a combination long lasting insecticidal net in areas of pyrethroid resistance

Helen Victoria Pates Jamet[1], Tessa B Knox[2]

[1]*Vestergaard Frandsen, Switzerland,* [2]*Vestergaard Frandsen, Kenya*

Increasing reports of pyrethroid resistance in many malaria-endemic countries have highlighted the need for tools with increased efficacy. A review of the evidence to support the function and efficacy of the first combination long lasting insecticidal net (LLIN) will be given. The rationale for the design of the tool will be presented including data to show that the net meets current WHO criteria for an LLIN. Results from experimental hut studies in 4 African countries will be presented showing increased efficacy against pyrethroid resistant malaria vectors. Differences in efficacy from country to country will be discussed in the context of the background resistance present in the target population where these studies were conducted. A comparison of the efficacy of the combination LLIN with a mono-treated LLIN at the village level will be presented. Finally, the utility of modelling to inform on community level effects expected with new products will be discussed. The type and scope of evidence required for decision-makers when new tools are introduced will be considered, both at the country level and at a global level.

[1]Ferdowsi University of Mashhad, Iran, [2]Masshad University of Medical Sciences, Iran, [3]Ferdowsi University of Mashhad, Iran, [4]Mashhad University of Medical Sciences, Iran

With regards to the role of cockroaches in transporting and distributing of various disease agents in remedial and hospital environments, the present study aimed to study the bacteria and fungi flora associated with the digestive system of Blattella germanica L. collected in spring and autumn (2010-2011) from different sections of a general hospital in Mashhad. Ten cockroaches were captured from each of 5 locations. After dissection of digestive system under sterile conditions, the extracts were incubated in EMB and Blood Agar medium. Bacteria and fungi were identified by clinic of microbiology of Imam Reza hospital of Mashhad. In autumn, the most prevalent bacterium was Enterococcus spp. (78%). Other bacteria consisted of Coagulase Negative Staphylococci, Staphylococcus aureus, Streptococcus spp., Escherichia coli, Klebsiella spp., Pseudomonas aeruginosa and Gram positive bacilli. In this season, 8 (out of 50) cockroaches were contaminated with fungi (16%), namely Penicillium spp. (50%), Mucor spp. (37.5%) and Aspergillus spp. (12.5%). In spring, the most prevalent species was Enterococcus spp. (48%). Other bacteria in this season consisted of Coagulase Negative Staphylococci, S. aureus, E. coli, Klebsiella spp., Tettragen spp., Citrobacter frondi, Serratia marsesens and Gram positive bacilli. In this season, 6 cockroaches were contaminated with fungi (14%), namely Penicillium spp. (14%), Mucor spp. (57%), Aspergillus spp. (14%) and Candida albicanse (14%). The results suggested that for reducing the risk of transmission of various disease agents, suitable control measures should be applied to manage the population of cockroaches in hospitals.

Expression profile analysis of detoxification genes in different life stages of *Anopheles funestus*

Riann N. Christian[1], Nanette Coetzer[2], Hilary Ranson[3], Riann N. Christian[4], Lizette L. Koekemoer[5]

[1]National Institute of Communicable Diseases, University of the Witwatersrand, South Africa, [2]University of Pretoria, South Africa, South Africa, [3]Liverpool School of Tropical Medicine, United Kingdom, [4]National Institute of Communicable Diseases, South Africa, [5]National Institute of Communicable Diseases, University of Witwatererand, South Africa

Anopheles funestus is a major vector of malaria in the southern African region and resistance to pyrethroids has been recorded in populations of this species. Quantifying differential expression of these genes at the different life stages of a mosquito will provide some insight into their role and function. Variation in the expression of these enzymes through the developmental stages in An. funestus is currently undocumented. The aim of this study was to therefore determine the transcription profile of the detoxification genes in the first instar, fourth instar and 3-day old adult mosquitoes, using the An. gambiae detox chip. Microarray analysis including dye labeling, hybridization, scanning and data analysis were performed. Results showed that in the fourth instar larvae and 3-day old adult comparison, 35 genes were overexpressed in the fourth instar larvae and seven genes in the adult stage. The comparison between first and fourth instar larvae, 67 genes showed increased gene transcription in the first instar larvae and nine genes in the fourth instar larvae. A total of 91 genes were overexpressed in the first instar larvae and five in the adults, when these two life stages were compared to each other. The differentially expressed genes in all life stages consisted mostly of cytochrome P450s, esterases, glutathione S-transferases and other additional genes. This study provided vital information regarding genes potentially involved in pyrethroid resistant and is the first to provide metabolic or detoxifying transcription gene information in An. funestus.

Physiological tolerances and species distribution modelling of two malaria vectors

Candice-Lee Lyons[1], Maureen Coetzee[2], John S. Terblanche[3], Steven L. Chown[4]

[1]Centre for Invasion Biology, Stellenbosch University, South Africa, [2]University of Witwatersrand, South Africa, [3]Stellenbosch University, South Africa, [4]Centre for Invasion Biology, Stellenbosch University, South Africa

A major concern associated with climate change is how changing rainfall patterns and temperature regimes will impact on the possible spread and distribution of vector-borne diseases (VBDs). In southern Africa, malaria is a VBD responsible for almost one million deaths annually. Information on the physiology of the mosquito vectors of the disease is largely lacking, despite its importance in determining the niche occupied by a species. Thermal tolerance, desiccation and starvation resistance, as well as development rate-temperature relationships were investigated for two of the most prominent malaria vectors in Africa: Anopheles arabiensis and An. funestus. On the whole, data suggest that females (the sex responsible for disease transmission) are more tolerant of environmental stress and changes to environmental conditions than males. Additionally, the ability of the immature forms (larvae and pupae) to withstand significantly greater temperatures than adults, suggests that breeding populations of Anopheles mosquitoes might be positively impacted by overall warming of global temperatures. Preliminary species distribution models indicate that at the boundaries of the malaria vectors' current distribution, and in regions where altitude and, by proxy, minimum temperatures, have been limiting to distribution, the potential for resurgence or emergence of malaria exists with changing climates.

Susceptibility of *Anopheles barbirostris* complex to *Plasmodium falciparum* and *Plasmodium vivax* in Thailand

Sorawat Thongsahuan[1], Visut Baimai[2], Anuluck Junkum[3], Atiporn Saeung[4], Wej Choochote[5]

[1]Prince of Songkla University, Thailand, [2]Faculty of Science, Mahidol University, Thailand, [3]Faculty of Medicine, Chiang Mai University, Thailand, [4]Faculty of Medicine, Chiang Mai University, Thailand, [5]Faculty of Medicine, Chiang Mai University, Thailand

Most Anopheles mosquitoes belong to species complexes is differences in malarial vector-competence among sibling species members. Recently, based on morphological, cytogenetic and crossing experiments and molecular investigation, at least 5 sibling species have been discovered within the taxon An. barbirostris in Thailand, i.e., An. campestris-like and An. barbirostris species A1, A2, A3, and A4. This study investigates the susceptibility of 5 sibling species to malaria parasites in laboratory conditions. Nine colonies of five sibling species members of An. barbirostris complexes were infected experimentally with P. falciparum and P. vivax. They were then dissected 8 and 14 days after feeding for oocyst and sporozoite rates, respectively, and compared with An. cracens. The results revealed that all of the mosquitoes in this experiment were completely refractory to P. falciparum. Likewise, An. campestris-like Forms E (Sa Kaeo) and F (Ayuttaya), and An. barbirostris species A4, were non-potential vectors for P. vivax. The lower than normal development of oocysts and sporozoites recovered from An. barbirostris species A1, A2 and A3, demonstrated that these species were low potential vectors for P. vivax. Only An. campestris-like Forms B and E (Chiang Mai) were high-potential vectors for P. vivax because normally high development of oocyst and sporozoite rates were obtained.

Possible factors that induce nocturnal activities of blow flies (Diptera: Calliphoridae)

Shih-Tsai Yang[1], Shiuh-Feng Shiao[2]

[1]National Taiwan University, Taiwan, [2]National Taiwan University, Taiwan

The ages of blow fly larvae that appeared on the corpses were used to estimate the post-mortem interval (PMI) of the victims in the criminal investigations. Thus the time gap between the blow fly oviposition and the death of a victim is a critical issue. Although blow flies have long been thought that they could not lay eggs at night, there are still several illustrations of nocturnal oviposition have been reported. Due to the limitation of oviposition sites for necrophagous blow flies, the locomotor activities such as searching and locating ability of the blow flies could highly affect their oviposition. According to the previous studies, circadian rhythm can regulate the fly locomotor activity and eye sensitivity. Since the blow flies are not active at night, our study is trying to find out if there is any possible factor that could break down the circadian rhythm of blow flies and thus induce their nocturnal activities or even the nocturnal oviposition under laboratory conditions. Our results suggested that the light is a possible factor that significantly increased the activity of blow fly at nighttime, but the temperature increase is otherwise not. If we simultaneously treated the blow flies with light and higher temperature at nighttime, there was no additional effect to their activities. These results may help to understand the nocturnal behavior of blow flies as well as to adjust the nighttime PMI estimation.

Gregarious oviposition of blow flies (Diptera: Calliphoridae)

Shiuh-Feng Shiao[1], Shih-Tsai Yang[2]

[1]National Taiwan University, Taiwan, [2]National Taiwan University, Taiwan

The ages of necrophagous blow fly larvae are commonly used to estimate the post-mortem interval (PMI) of victims or animals in forensic entomology, thus the blow fly oviposition, the starting point of a fly life history, becomes an important factor in those applications. Oviposition behavior also plays a very important role in the evolutionary adaptation for a species. Under the limited carrying capacity of the larval resource, the clutch size produced by parental females may influence the progeny competition and fitness. Therefore, insects seldom show gregarious oviposition behavior, which means several females oviposite at the same site or even in a cluster. But the blow flies seem to be one of the exceptions; in the field, several blow flies usually lay large amount of eggs on the same carcass. To understand the gregarious effects on blow fly oviposition, we test the fecundity of Chrysomya megacephala (Fabricius) (Diptera: Calliphoridae) under different coexisting amounts and types of blow fly companies. Results showed the blow flies rarely lay egg when alone. And gregariousness not only induced the oviposition behavior but also increased the clutch size for each individual. In addition, different types of blow fly companies, such as different sexes or species, could also affect the oviposition performance. Our study herein proposes the significant effects of gregarious behavior on oviposition, and we presume these results may have potential usage in forensic investigation, especially when using blow fly thermo history on PMI estimation.

Body size measurements as quality indicators in *Aedes aegypti* mosquitoes destined for field release

Heng Lin Yeap[1], Nancy Margaret Endersby[2], Petrina Johnson[3], Scott Ritchie[4], Ary Anthony Hoffmann[5]

[1]*Bio21 University of Melbourne, Australia,* [2]*Bio21 University of Melbourne, Australia,* [3]*James Cook University, Australia,* [4]*James Cook University, Australia,* [5]*Bio21 University of Melbourne, Australia*

There is increasing interest in rearing modified mosquitoes for mass release to control vector-borne diseases, including release of Wolbachia-infected Aedes aegypti mosquitoes for suppression of dengue. Successful manipulations of natural populations require the release of high quality mosquitoes. Potential simple quality indicators are body size and related measurements. Here we test if size and wing/thorax ratio, (thought to be related to flight ability), can be related to field fitness of Wolbachia-infected A. aegypti. Released mosquitoes were much larger on average than field-collected populations and the variance was much smaller. Wing/thorax ratios had lower overall variation with less distinct differences between released and field mosquitoes. We monitored the 2011 trial release of Wolbachia-infected A. aegypti and found that over time, Wolbachia-infected A. aegypti bred in the field achieved similar variance to the wild population. Based on the size differences of field and release mosquitoes, we estimated that the survival of released mosquitoes was comparable to field mosquitoes. By collecting infected adult females from sticky traps during an open field release, we showed that within the limited variance of field cage reared mosquitoes, there was no evidence for size-related selection, either in terms of females feeding and reaching oviposition sites or survival. However within uninfected field mosquitoes collected from traps, gravid females tended to be larger than others suggesting an advantage for larger females. These findings suggest that, for females, size is a useful fitness indicator and rearing conditions should aim for large size without unduly affecting wing size/thorax ratios.

Effectiveness of Bti-based product from Bti cells cultivated by using glutamic acid mother liquor, a waste of monosodium glutamate production

Laojana Chowanadisai[1], Nuntaporn Phonsuwan[2], Pornchai Wiriyasaranond[3], Narong U-Mai[4]

[1]National Institute of Health, Thailand, [2]National Institute of Health, Thailand, [3]National Institute of Health, Thailand, [4]National Institute of Health, Thailand

The present study was aimed at utilization of glutamic acid mother liquor (GM1), a waste of monosodium glutamate production, as cultivation medium for B. thuringiensis subsp. israelensis (Phrae strain) and assessment on the larvicidal activity of Bti-based product against Aedes aegypti larvae. Results indicated that initial pH of 7.2-7.8, temperature of 30-34 oC and aeration of 150-250 rpm were appropriate environment for cultivation of candidate strain. Among a dilution series of GM1, GM1 at 1:8 exhibited the highest amount of cell mass of 3.976 g/l while those of GM1 at 1:64 gave the lowest of 0.635 g/l. The highest larvicidal activity against Aedes aegypti was found from GM1 at 1:64 while those of GM1 at 1:8 showed the lowest. Increase of cell mass by supplementing 0.2 g/l of glucose in GM1 at 1:64 was promised. A submerge fermentation under weather temperature and 282 rpm indicated that steady state was recorded at 39th hours after inoculation. pH varied from 6.59-8.18. The cells during 18-30 hours of age showed the best larvicidal activity with non statistical difference. The potency of the cells from GM1 plus glucose was 14,370 ITU/mg. A tablet form of product coded NIH-BT 2011 was performed for simulated field evaluation. After 7 months of monitoring the shelf life of product, reduction of larvicidal activity was not yet noticed. The duration that product provided more than 90% larval mortality when water in the containers was 25, 50 and 90% removed and replaced, were 45, 40 and 25 days, respectively.

The effect of blood feeding on gene expression in insecticide resistant *Anopheles funestus*

Belinda Lea Spillings[1], Basil Desmond Brooke[2], Maureen Coetzee[3], Lizette Koekemoer[4]

[1]National Institute for Communicable Diseases, South Africa, [2]National Institute for Communicable Diseases, South Africa, [3]School of Pathology University of the Witwatersrand, South Africa, [4]National Institute for Communicable Diseases, South Africa

Indoor spraying of houses with residual insecticides (IRS) is the mainstay of many malaria vector control programs in Africa. IRS targets resting adult female Anopheles mosquitoes before or after blood feeding. During blood feeding, the mosquito may ingest toxic xenobiotics present in the host's blood. In the resting period after feeding, many processes are initiated to assist in the digestion and assimilation of the blood nutrients. Since the regulation of xenobiotic (including insecticides) detoxification enzyme systems is likely to be altered in response to the ingestion of blood, this study aimed to investigate the effect of a blood meal on insecticide tolerance in insecticide resistant and susceptible southern African strains of the major malaria vector Anopheles funestus. We have demonstrated that blood fed An. funestus, carrying a resistance phenotype, are able to tolerate higher doses of insecticide than their unfed counterparts. Microarray studies on these blood-fed mosquitoes showed a general increase in delta class glutathione-s-transferase (GST) expression. An An. funestus orthologue of the GSTD3 gene was investigated as a target for qRT-PCR, but the results were inconclusive. Since the pyrethroid resistant phenotype of southern African An. funestus has been linked to the over-expression of the duplicate copy gene CYP6P9, the expression of CYP6P9 and CYP6P13 were quantified. Both genes showed a small, but significant, increase in response to the blood meal. The increased expression of these major effect CYP6 genes in response to blood feeding may be responsible for the increase in insecticide tolerance seen in the bioassays.

Characterization of akirin in the South African malaria vector *Anopheles arabiensis*, and its importance as a novel tool to serve as a vector control intervention.

Annette Bennett[1], Riann Christian[2], Christine Maritz-Olivier[3], Lizette L. Koekemoer[4]

[1]*Vector Control Reference Unit, Centre for Opportunistic, Tropical and Hospital Infections, South Africa,* [2]*Vector Control Reference Unit, Centre for Opportunistic, Tropical and Hospital Infections, South Africa,* [3]*University of Pretoria, South Africa,* [4]*Malaria Entomology Research Unit, School of Pathology, Faculty of Health Sciences, WITS, South Africa*

The malaria parasite (Plasmodium spp.) is transmitted to humans by various Anopheles spp., with over 90% of human infections occurring in sub-Saharan Africa. The Anopheles gambiae complex compromises of seven species, whereof two species are considered as major malaria vectors in tropical Africa, An. gambiae s.s. and An. arabiensis. In order to enhance South Africa's malaria control capacity, additional vector control tools are investigated for their practical incorporation into existing control programmes. Other researchers have shown that a tick specific vaccine, subolesin, provides protection against tick-borne pathogens. This study aimed to characterize the orthologous gene, akirin, in An arabiensis, and phylogenetically compare it to other closely related species, i.e. An merus, An. gambiae and An. quadriannulatus. Preliminary results achieved have confirmed a high level of sequence identity between akirin in An. arabiensis and other insects. The potential of akirin, as a tool for further use in immunization studies on the fitness of An. arabiensis will be examined. It is expected to reduce mosquito survival, feeding rate and reproduction after feeding experiments on a host vaccinated with recombinant tick and Aedes albopictus akirin. The application for in vivo gene silencing and phenotype assessment of An. arabiensis feeding on subolesin using double-stranded RNA (dsRNA) is discussed.

Malaria is caused by parasites Plasmodium genus transmitted by Anopheles mosquitoes during the blood feeding. During this blood meal, saliva and parasites are injected into the vertebrate host skin. Salivary molecules possess a pharmacologic role allowing correct blood feeding and counteracting the acquired host immune response throught their immunomodulation properties. It has been demonstrated that the expression of salivary proteins of Anopheles gambiae infected by Plasmodium berghei are modified. Here we investigate what modifications in salivary glands of An. gambiae occur during the infection by wild P. falciparum. To assess this question we compare salivary extracts of An. gambiae infected and uninfected by proteomic approach. Experimental infections of An. gambiae by wild P. falciparum are carried out in Cameroon and salivary glands are dissected 14 days post-infection. The quantitative-PCR allowed to quantify the P. falciparum infection into the salivary glands. Two-Dimensional Differential Gel Electrophoresis (2D-DIGE) are underway with different pools of non-infected versus infected salivary glands. Preliminary results showed that several components are over- or down-expressed during the infection. Mass spectrometry analysis will reveal differentially expressed proteins. These results suggest that the parasite surely induces modifications of salivary proteins expression, certainly favoring its transmission. This study will give us more knowledge about the relationships between the vector and its host and may lead to the developpment of new tools to better evaluate the risk of malaria transmission, like an immuno-epidemiologic biomarker. These observations represent important new applications for evaluation of vector control strategies

Electric nets and sticky materials for studying oviposition behaviour of gravid malaria vectors

Sisay Dugassa[1], Jenny Lindh[2], Steve Torr[3], Florence Oyieke[4], Steve Lindsay[5], Ulrike Fillinger[6]

[1]International Centre of Insect Physiology and Ecology (ICIPE), Ethiopia, [2]ICIPE, Sweden, [3]ICIPE, United Kingdom, [4]ICIPE, Kenya, [5]London School of Hygiene and Tropical Medicine (LSHTM), United Kingdom, [6]London School of Hygiene and Tropical Medicine (LSHTM) and ICIPE, Germany

Indoor sampling of Anophels gambiae s.l., the major malaria vector in sub-Saharan Africa, has become difficult due to continued insecticide use inside houses. Alternative sampling tool need to be developed to collect vectors outdoors. One target could be a gravid female in search for an oviposition site but little is known how this vector approaches and selects suitable habitats and how eggs are deposited. In order to study this behaviour we developed electrocuting nets (e-nets) and various sticky materials under semi-field condition using insectary ? reared An. gambiae s.s.. E-nets proofed to work well for the collection of anophelines orienting towards an odour source when the nets were electrified in such a way that no visual sparks were generated ($p<0.001$).Furthermore, it was necessary to develop a collection device below the e-nets where stun mosquitoes were contained which was by itself not attracting mosquitoes. Three different sticky materials were tested, a transparent film, a yellow film and a black netting with insect glue. The transparent and black surfaces were highly attractive for gravid anophelines as compared to the yellow film ($p<0.001$) and could play a potential role as gravid traps in the future. Sticky materials and detergents were used to study landing on the water surface or on the edge of habitats for oviposition. Significantly, more An. gambiae females land directly on the water surface to deposit their eggs than on the edge of habitats ($p<0.001$). Implications of the results for the development of gravid traps will be discussed.

Development of *Plasmodium berghei* in *Anopheles funestus*

Te-chang Mike Lo[1], Lizette Leonie Koekemoer[2], Maureen Coetzee[3]

[1]National Institute for Communicable Diseases; University of the Witwatersrand, South Africa, [2]National Institute for Communicable Diseases; University of the Witwatersrand, South Africa, [3]National Institute for Communicable Diseases; University of the Witwatersrand, South Africa

Anopheles funestus is a major malaria vector in Sub-Saharan Africa, efficient in its vectorial capacity and is highly anthropophilic and endophilic. Despite its importance, research on the species has been severely limited due to a lack of laboratory colonies until 2000. An infection model using Plasmodium berghei with An. funestus was successfully established recently, but details of the parasite development remains largely unknown. To investigate the development, adult females from the base An. funestus colony FUMOZ was allowed to feed on C57/Black mice infected with ANKA strain of P. berghei. The bloodfed females were maintained at 21±1°C, 85±10% relative humidity and provided with 10% (w/v) sucrose water for sustenance. Midgut and salivary glands dissection were performed to determine the appearance of oocysts and sporozoites in the two organs respectively, and to quantify the infection. Oocysts were seen 10-12 days after the infected bloodmeal, and sporozoite appeared 18-21 days post bloodmeal. Average oocyst number was around 25, leading to 2-3 000 sporozoites in the salivary glands. Infected females were able to initiate cyclical transmission upon feeding on a healthy mouse, demonstrating the viability of the parasite. The results showed that P. berghei development in An. funestus is longer than in other vectors. Quantification of the life stages indicate that Anopheles funestus is not as an efficient vector of P. berghei compared to An. Stephensi, but is better than An. quadrimaculatus. Nonetheless, it is still a viable vector, and the parasite development data will be of use for future studies.

Aedes aegypti and *Aedes albopictus* breeding recepticles and their association with the number of dengue cases reported

Waseem Akram[1], Jong Jin Lee[2], Hafiz Azhar Ali Khan[3]

[1]Chief Minister's Secretariat, Pakistan, [2]Chonbuk National University, Republic of Korea, [3]BZ, University Multan, Pakistan

Aedes populations were collected during the epidemic period starting from July 2011 and going up to the end of Nov 2011. Both indoor and out door survveillance was done and all indices were recorded. The vector was breeding extensively in all major recepticles. The most potential out door breeding site included the automobile tyres, construction sites, plastic wrappers, scrap dumping areas. While the major indoor breeding sites included those houses where the water supply was limited to few hours and water containers were used for storing water either for consumption or washing. The water containers along with the underground and over head water tanks were found positive for the Aedes larvae. As for the percentage of the species dominance is concerned the Aedes albopictus was more confined to out door while Aedes aegypti was dominating the indoor premises like the refrigerator trays, room coolers, roof tops blocked spill ways on roof tops etc . The population peaks were recorded from end July 2011 and continued till mid October 2011, there after the population declined to very few breeding sites. No population was collected during the months of December 2011 to end of February 2012 despite the early spring showers in end of February 2012. First population was reported within the houses in water storage containers in the first week of March 2012 that included the Aedes aegypti larvae. A strong association of the breeding sites and the number of dengue infected cases was recorded during the 2011 epidemic.

Population genetic structure of the major malaria vector *Anopheles funestus* s.s. and allied species in southern Africa

Kwang Shik Choi[1], Lizette L. Koekemoer[2], Maureen Coetzee[3]

[1]School of Pathology, Faculty of Health Sciences, University of the Witwatersrand, South Africa, [2]National Institute for Communicable Diseases, National Health Laboratory Service, South Africa, [3]School of Pathology, Faculty of Health Sciences, University of the Witwatersrand, South Africa

Anopheles funestus sensu stricto is one of the major malaria vectors in sub-Saharan Africa belonging to a group of ten morphologically similar species. The population structure of An. funestus s.s. based on mitochondrial DNA data led to the description of two cryptic subdivisions, clade I widespread throughout Africa and clade II known only from Mozambique and Madagascar. We investigated five common members of the Anopheles funestus group including An. funestus s.s. clades I and II in order to determine relationships within and between species. The population genetic structures of An. funestus s.s., An. funestus-like, An. parensis, An. rivulorum and An. vaneedeni from South Africa, Mozambique and Malawi were assessed using NADH Dehydrogenase subunit 5 (ND5) and Cytochrome Oxydase I (COI) within and between populations. The phylogenetic trees for both genes revealed three main lineages: 1) An. rivulorum, 2) An. funestus-like and 3) Anopheles funestus subgroup including An. funestus s.s. clades I and II, An. parensis and An. vaneedeni. Interestingly, An. funestus-like, An. parensis and An. vaneedeni exhibited two clades each. This is the first report comparing An. funestus group species including An. funestus clade I and II and the new species An. funestus-like. Anopheles funestus clade I is separated from the rest members of the An. funestus subgroup within the lineage and An. funestus-like is distinctly distributed from the other species in this study. Further investigations are needed to determine what these results mean in terms of their specific status.

DNA barcoding of the mosquito genus *Culex* (Diptera, Culicidae)

Yvonne-Marie Linton[1], Jacques Dubois[2]

[1]*Natural History Museum, United Kingdom,* [2]*Natural History Museum, United Kingdom*

Culex is a large cosmopolitan genus of mosquitoes. Several species are vectors for arboviruses (e.g. West Nile and Japanese encephalitis viruses) and filarial worms that cause disease in humans. To facilitate an effective management of both mosquitoes and diseases, accurate identification of vectors is a key element. Within the framework of the Mosquito Barcoding Initiative, which aims to produce identification tags for 80% of all currently recognized species of Culicidae (3531 species), and in conjunction with an ongoing integrated morphological and molecular systematics study of the tribe Culicini at The Natural History Museum in London, we carried out barcoding of Culex species to provide reliable identification tools. To achieve our sampling, we relied heavily on archive specimens in major museums of the world. We investigated the utility of the COI barcode region for species identification across the genus Culex and other members of the tribe Culicini. We discuss the power of resolution of DNA barcoding and its limitations for reliable identification of specific and subspecific taxa and members of cryptic species complexes, as well as the use of barcodes as a possible tool to uncover genetic variability that may lead to the discovery of new taxa.

Effect of Ketamine hydrochloride on the development of a forensically important blow fly *Chrysomya megacephala* (Fab.) (Diptera: Calliphoridae)

Devinder Singh[1], Bhupinderjeet Kaur[2]

[1]*Punjabi University, India,* [2]*Punjabi University, India*

Entomotoxicology is a specialized area of forensic entomology that deals with the qualitative and/or quantitative determination of toxic substances (e.g. drugs, environmental pollutants, pesticides) in insects and other arthropods feeding on human remains. These natural scavengers can serve as a source for toxicological analysis when the tissues or body fluids normally used for this purpose are not available. Qualitative determination of toxic substances and drugs can add information on both the cause of death and the geographical area where the cadaver had been lying. Since toxic substances can modify the biological cycle of arthropods, their quantitative determination provides an additional parameter for evaluating the post-mortem interval (PMI). Ketamine hydrochloride is a Schedule 'H' drug used in human and veterinary medicine. It produces dissociative anaesthesia and is commonly abused as a recreational drug. It has also gained notoriety as a 'date-rape' drug and may be found in cases of drug overdose related deaths or in suspected drug assisted rape and murder assaults. The objective of this study was to analyze its effect on the development of immature stages of Chrysomya megacephala (Fabricius) reared on rat tissues containing Ketamine hydrochloride administered antemortem. The presence of Ketamine hydrochloride could be detected through Gas chromatography (GC) in all the rat samples and in almost all fly samples in the experiment. Results show good correlation between the quantity of Ketamine hydrochloride administered and the rate of development of the immature stages of this forensically important fly.

Background: Measuring human exposure to arthropod bites, would allow estimating transmission risk of certain vector-borne diseases. Aedes aegypti mosquito is the primary vector of arboviruses such as dengue, Chikungunya and yellow fever. The present study aim at evaluating human specific antibody (Ab) IgG response to Aedes aegypti salivary peptide (the Nterm-34kDa peptide) and its potential use in measuring exposure to Aedes aegypti bites. Methodology/principal findings: A longitudinal study, concerning children (n=205, aged from 0 to 5 years) living in an area where Ae. aegypti is endemic in southern Benin (West Africa), was performed between 2008 and 2009. For each child, the specific immune response against the Nterm-34kDa peptide was evaluated by ELISA method, from a dried blood spot on filter paper collected every 6 weeks. The results demonstrated the existence of a specific IgG Ab response to Nterm-34kDa peptide in children exposed to Aedes aegypti bites. This response increased significantly for each year, from the dry season (low exposure) to the rainy season (high exposure). In addition the IgG Ab level was associated to the intensity of rainfall and presented spatial heterogeneity between individuals and between the studied villages. Conclusions/Significance: This preliminary study showed that IgG Ab responses to the candidate Nterm-34 kDa could be a promising alternative for evaluating the level of exposure to Aedes vectors and then the potential risk for getting arboviruses. It will be essential to validate this immuno-epidemiological tool by conducting further studies taking into account entomological measurements.

Preliminary study on Ketosynthase gene in *Paederus* Fabricius

Zhiping Liu[1], Jinjun Wang[2]

[1]College of Plant Protection, Southwest University, China, [2]College of Plant Protection, Southwest University, China

The degenerate primers of Ketosynthase (KS) gene were designed and in total 11 species of Paederus were amplified. Only females of P. fuscipes from 4 different collections were amplified with a fragment of about 1000 bp, named pedKS gene. pedKS gene is homologous with the KS gene of Pseudomonas to 76%-86%. NJ phylogenetic tree of representative KS gene from NCBI shows that pedKS gene possesses a close phylogenetic relationship with FAD-dependent oxidoreductase gene. Homologous gene in Pseudomonas fluorescens with pedKS synthesizes pyridine six membered rings by redox reaction. It is predicted that pedKS may also participate in the synthesis of pyran six rings in Pederin by oxidation reduction.

Synchrotron X-ray microtomography and digital 3D imaging for examining insect morphology

Thomas van de Kamp[1], Tomy dos Santos Rolo[2], Patrik Vagovic[3], Alexander Riedel[4], Tilo Baumbach[5]

[1]Karlsruhe Institute of Technology (KIT), Germany, [2]Karlsruhe Institute of Technology (KIT), Germany, [3]Karlsruhe Institute of Technology (KIT), Germany, [4]State Museum of Natural History Karlsruhe, Germany, [5]Karlsruhe Institute of Technology (KIT), Germany

Due to their exoskeleton, internal morphological features of insects are often difficult to examine by traditional methods like light and electron microscopy. As synchrotron X-ray microtomography (SR-µCT) allows non-destructive imaging of millimeter-sized objects, it became a powerful tool for entomologists and was already considered a "methodological milestone in micro-anatomical research" (Betz et al. 2007). High-speed SR-µCT reduces the duration of a full tomographic scan to just a few seconds. Apart from dried samples, even ethanol-preserved specimens can be processed inside their containers without causing the fluid to boil. To analyze the image stacks, it is crucial to decide what visualization method is suitable to approach a particular scientific question. Volumetric data can be visualized by voxel-based volume renderings or by polygon surfaces based on labeled structures inside the image stack. Volume renderings are very suitable to quickly visualize objects as a whole. Further, virtual slices of selectable thicknesses allow examination of internal structural details without losing the 3D impression, as exemplified here for the head of the stick insect Peruphasma schultei (Fig.). While the creation of polygon surface models is time-consuming, it allows moving distinct body parts of a specimen with respect to each other. This method was used to interactively analyze and visualize the three-dimensional movements of the coxa-trochanteral joints of the weevil Trigonopterus oblongus, which constitute biological screw-and-nut systems.

Origin of the luminescence system in firefly

Yuichi Oba
Nagoya University, Japan

Bioluminescence is one of the most fascinating phenomena in insects. The luminescence mechanism, luciferin-luciferase reaction, has been intensively studied using fireflies (Lampyridae). In contrast, the evolutionary aspects of the luminescence system remain obscure. I have studied on the origin of firefly luciferase and found that: (1) firefly luciferase arose from an enzyme involving in lipid metabolic pathway; (2) then, gene duplication gave rise to functionally different paralogues; (3) one of which is used for the luminescence in adult and another is for egg.

Formation of germ band in Diplura, with special reference to the differentiation of germ layers (Hexapoda)

Kaoru Sekiya[1], Ryuichiro Machida[2]

[1]University of Tsukuba, Japan, [2]University of Tsukuba, Japan

Diplura are included in Entognatha together with Protura and Collembola. However, some doubts have been cast on the monophyly of Entognatha, and recently a sister group relationship between Diplura and Ectognatha was suggested from various disciplines. Thus, Diplura are one of the most significant members in understanding the groundplan and reconstructing the phylogeny of hexapod basal clades. Uzel (1898) described the germ band formation in a rhabduran dipluran Campodea staphylinus Westwood. It is absolutely unique not only among Hexapoda but among Arthropoda, accompanied by peculiar manner of germ layer segregation, and the re-examination of the germ band formation in Diplura had been desired for long time (Jura, 1972). Ikeda (2001) light- and electron-microscopically observed the germ band formation in another rhabduran dipluran Lepidocampa weberi Oudemans, and reconfirmed the Uzel's observation. However, the information on dipluran germ band formation is still scanty and fragmented, and in addition our knowledge on it concerns only the suborder Rhabdura, that for another dipluran suborder Dicellurata being totally lacking. Aiming at the comprehensive understanding of the germ band formation in Diplura, we have been studying that in a dicelluratan Occasjapyx japonicus (Enderlein), also referring to the embryogenesis of a rhabduran L. weberi.

The spruce budworm genome takes flight: Current endeavours and direction in sequencing the *Choristoneura fumiferana* genome

Michel Cusson[1], Halim Maaroufi[2], Audrey Nisole[3], Brian Boyle[4], Jerome Laroche[5], Catherine Beliveau[6], Irena Kukavica-Ibrulj[7], Daniel Doucet[8], Christopher Lucarotti[9], Felix Sperling[10], Lisa Lumley[11], Bryan Brunet[12], Heather Bird[13], Vince Nealis[14], Roger Levesque[15]

[1]Natural Resources Canada, Canada, [2]Universite Laval, Canada, [3]Universite Laval, Canada, [4]Universite Laval, Canada, [5]Universite Laval, Canada, [6]Natural Resources Canada, Canada, [7]Universite Laval, Canada, [8]Natural Resources Canada, Canada, [9]Natural Resources Canada, Canada, [10]University of Alberta, Canada, [11]Natural Resources Canada, Canada, [12]University of Alberta, Canada, [13]University of Alberta, Canada, [14]Natural Resources Canada, Canada, [15]Universite Laval, Canada

The spruce budworm (Choristoneura fumiferana) (Lepidoptera: Tortricidae) is North America's most devastating defoliator of conifer trees and a model organism for the study of insect outbreak dynamics. This species is also part of a larger species complex, where the species are largely associated with different geographic ranges and host plants, allowing the group as a whole to be fascinating in the study of adaptation and speciation. Sequencing and assembling the C. fumiferana genome will provide researchers with a much needed tool to further study this group of forest insect pests. Our sequencing strategy combines several NGS technologies including: (i) Roche 454 GS-FLX and GS-FLX+ shotgun sequencing, (ii) GAIIx Illumina sequencing of a 2 kb paired-end library, (iii) 454 GS-FLX sequencing of 6 kb and 20 kb paired-end libraries, and (iv) 454 GS-FLX+ sequencing of pools of 50 BAC clones (average insert size of 140 kb). For identification of expressed ORFs during the annotation process, we have also conducted 454 GS-FLX+ sequencing of a normalized cDNA library developed from a pool of RNAs extracted from all budworm life stages. These transcriptomics resources complement existing EST libraries developed by our group. Several companion studies include Illumina sequencing and mapping of other Choristoneura species, inter- and intraspecific genotyping-by-sequencing studies, and tissue-specific RNA-seq transcriptomics. Here, we will report our progress to date in assembling and annotating the genome, and further describe the companion studies that are currently underway.

Entomotoxic and membrane-disturbing properties of urease and derived peptides

Celia Regina Ribeiro da Silva Carlini[1], Anne H. S. Martinelli[2], Angela Regina Piovesan[3], Karine Kappaun[4], Cristian Follmer[5], Jean-Louis Schwartz[6]

[1]Federal University of Rio Grande do Sul, Brazil, [2]Federal University of Rio Grande do Sul, Brazil, [3]Federal University of Rio Grande do Sul, Brazil, [4]Federal University of Rio Grande do Sul, Brazil, [5]Federal University of Rio de Janeiro, Brazil, [6]Universite de Montreal, Canada

Ureases, enzymes that catalyze the hydrolysis of urea into ammonia and CO2, also display biological properties unrelated to ureolysis, such as fungitoxic and insecticidal activities. Plant ureases are lethal to insects not susceptible to Bt toxins. In the case of jackbean urease (JBU), insecticidal activity relies mostly on an internal peptide (jaburetox-2) released by the insect's digestive enzymes. However, whole ureases show entomotoxic properties per se. Here urease and derived peptides were tested for membrane-disturbing properties using Planar Lipid Bilayers (PLB) and the carboxyfluorescein release assays. Aiming to establish structure X activity relationships, Jaburetox-2 mutants were obtained: deletion of aminoacids 61-75 (deltaBeta-hairpin); deletion of N-terminal (delta1-44) and of the C-terminal (delta45-92) halves. JBU and Jaburetox-2 (5-10 nM) inserted into the PLB forming ionic channels. JBU's channels displayed conductance levels of 1730, 833, 625 and 352 pS, with apparent anion selectivity. Jaburetox-2 also forms channels with different conductance and kinetics. Jaburetox-2 (72 nM) induced leakage of carboxyfluorescein from large unilamellar vesicles composed of acidic lipids. The deltaBeta-hairpin mutant showed all the properties of wild jaburetox-2, indicating that the Beta-hairpin motif is not relevant for its membrane-disturbing ability. The halves of jaburetox-2 molecule (delta1-44 and delta45-92) showed much decreased activity on PLB and carboxyfluorescein leakage assays, suggesting the presence of an active domain that was "split" between these two mutants. Membrane-disturbing and ion channel forming activities of urease and derived peptides may contribute to their diverse biological activities, as plant defense against insects and pathogens. Financial support: CAPES, CNPQ, FAPERGS, SEVE Centre.

Differences in egg morphology between coleopteran and lepidopteran stored-product insect pests in relation to tolerance to fumigants

Sandipa G. Gautam[1], George P. Opit[2], Spencer Walse[3], Dennis Margosan[4]

[1]Oklahoma State University, U.S.A., [2]Oklahoma State University, U.S.A., [3]USDA-ARS San Joaquin Valley Agricultural Sciences Center, U.S.A., [4]USDA-ARS San Joaquin Valley Agricultural Sciences Center, U.S.A.

Eggs of Coleoptera are more tolerant to fumigants than those of Lepidoptera. Driedfruit beetle (DFB, Carpophilus hemipterus, Coleoptera: Nitidulidae) and navel orangeworm (NOW, Amyelois transitella, Lepidoptera: Pyralidae) are endemic to California and pose a threat to the California dried fruit and nut industry. Post-harvest chamber fumigation is a critical element of the DFB and NOW pest management strategy. However, eggs of DFB are difficult to kill using sulfuryl fluoride. Therefore, we studied the external morphology of DFB and NOW eggs using a scanning electron microscope to identify any structural differences that may explain their differential response to sulfuryl fluoride. We found that aeropyles, which enable gaseous exchange in eggs, are few (2) in DFB and restricted to only one end of the egg. On the other hand, NOW has a greater number of aeropyles (7) distributed on both ends of the egg. The micropyle, which is an opening for sperm entry that also facilitates gaseous exchange, is absent in DFB but present in NOW. It is possible NOW eggs with a micropyle and several aeropyles may have a higher rate of fumigant penetration than DFB. In DFB eggs with only 2 aeropyles, the route for fumigant entry may predominantly be diffusion through the chorion. However, fumigant entry into the egg by diffusion through the chorion may be comparatively slower compared to entry through aeropyles and/or micropyle. Our findings provide a possible explanation for why coleopteran eggs are more tolerant to fumigants than lepidopteran eggs.

Analysis of a chromosomal region harboring the sex determination locus in the yellow fever mosquito *Aedes aegypti*

Elzbieta Krzywinska[1], Vladimir KoKoza[2], Marion Morris[3], Elena de la Casa-Esperon[4], Alexander Raikhel[5], Jaroslaw Krzywinski[6]

[1]Liverpool, United Kingdom, [2]University of California, Riverside, U.S.A., [3]Liverpool School of Tropical Medicine, United Kingdom, [4]Universidad de Castilla-La Mancha, Spain, [5]University of California, Riverside, U.S.A., [6]Liverpool School of Tropical Medicine, United Kingdom

Aedes aegypti is a major vector of viruses infecting up to 100 million people annually. Genetic approaches to Aedes control hold promise for a successful management of these diseases, but creation of the necessary tools depends on the knowledge of developmentally-regulated sex-specific mosquito genes. We constructed an A. aegypti strain (C42), in which a single transgene insertion occurred within a repetitive sequence tightly linked with the maleness locus on chromosome 1. As a result, males from this strain possess an eye promoter-controlled EGFP tag. However, rare crossing-over events during male meiosis break the linkage between the maleness locus and the transgene. We established two recombinant lines (A and B), in which females carry the EGFP-positive chromosome 1. Females of line A crossed to any male produce progeny with a distorted sex ratio (1♂:2♀), because all F1 embryo males inheriting the maternal recombinant chromosome 1 die. Moreover, crosses involving double recombinant females that secondarily lost EGFP during crossing-over yield progeny with an inverted sex ratio (2♂:1♀), also caused by embryonic lethality. Line B females produce progeny with a Mendelian inheritance pattern; however, inbreeding the EGFP-inheriting progeny leads to homozygote females that die during emergence from pupae. These results indicate the existence within the recombination region of genes vital for sex-specific development, whose location safeguards against homogenization of gender-specific sex determining loci. The described lines represent a unique resource to molecularly identify all the loci involved.

Egg structure and embryonic development of *Eucorydia yasumatsui* Asahina (Blattodea, Polyphagidae)

Mari Fujita[1], Ryuichiro Machida[2]

[1]*University of Tsukuba, Japan,* [2]*University of Tsukuba, Japan*

Although an assemblage of the Blattaria, Mantodea and Isoptera or the Dictyoptera is well supported to be monophyletic, the systematic relationships between three ordinal constituents have not been settled, despite a lot of morphological and molecular phylogenetic studies, besides, which often bestow a paraphyletic status to Blattaria. Therefore, for the reconstruction of groundplan of Dictyoptera and their phylogeny, the understanding of Blattaria is the most significant. For the solution of phylogenetic problems, the comparative embryological approach is promising. Many embryological studies have been made on Blattaria. However, they concern only the species well known as pests of the derived families Blattellidae (Blattella germanica) and Blattidae (Periplaneta spp., Blatta orientalis), and it is difficult to figure out the embryological groundplan of Blattaria. In such a background, we have planned a comparative embryological study covering the representative members of cockroaches from primitive to advanced. As the first step of our study, we tackled with Polyphagidae, which is one of the proposed basalmost clades in Blattaria, using a Japanese polyphagid Eucorydia yasumatsui Asahina. We show the structural features of its eggs and provide an outline of its embryonic development. The eggs are provided with several micropyles on their posterior ventral side. The embryo forms at the ventral side of the egg, and develops there without changing its original position and axis, as in the embryos of Blattellidae. A drastic changing of embryo's axis as shown in the embryos of Periplaneta and Blatta is not involved in the blastokinesis of E. yasumatsui.

Weevil evolution and differential gene expression in the development of the rostrum

Steven R. Davis[1], Paulyn Cartwright[2], Michael Engel[3]

[1]University of Kansas, U.S.A., [2]University of Kansas, U.S.A., [3]University of Kansas, U.S.A.

Weevils (Coleoptera: Curculionoidea) are a diverse group of extant organisms with approximately 50,000 described species. They are of great agricultural significance because they are associated with all major groups of plants and plant tissues. The weevil rostrum, for example, is a key evolutionary innovation that has enabled this group to feed on and oviposit in nearly all plant tissues, giving rise to diverse life histories and tremendous diversity in rostrum form. Insights into comparative development of the rostrum will provide insight into the evolution of this key innovation that may be responsible for the explosive radiation of the lineage. Although weevils are an enormous group and countless species are significant agricultural pests, no weevil species have been utilized in developmental studies. In order to better understand the formation and evolution of this structure, histological examinations have been made in a phylogenetic context for comparing the internal structure of the rostrum in adults. Transcriptomes from the developing head tissue of 4 weevil species, representing disparate clades and divergent rostral forms, and 1 outgroup (non-weevil species) have also been produced in de novo assemblies. While there are difficulties in assessing differences among transcriptomes from divergent taxa, tests for differential expression patterns of transcripts are being performed to characterize differences in the gene networks that are producing the profound phenotypic diversity observed in the rostrum and to better understand the genetic framework that permitted the diversification of such an immense lineage as the weevils.

Microsatellite markers in the era of Next-Generation DNA sequencing: Informative and cheap genetic markers for entomological research

Thibaut Malausa[1], Andre Gilles[2], Emese Meglecz[3], Stephanie Ferreira[4], Jean-Francois Martin[5]

[1]UMR ISA (INRA, UNSA, CNRS), France, [2]Centre Saint-Charles, France, [3]Centre Saint-Charles, France, [4]Campus de l'Institut Pasteur, France, [5]Campus International de Baillarguet, France

Microsatellites are among the most frequently used DNA markers in many areas of research, including entomology. These genetic markers can be developed for non-model species and are highly informative when investigating genetics and dynamics of insect populations: genetic structure of populations, estimation of gene flow between taxa, patterns of fine-scale dispersion, determination of pest insect invasion routes, etc. This presentation first summarizes the main advantages of microsatellite markers and gives several examples of their use in entomology. Second, it focuses on the new perspectives open by Next Generation DNA sequencing that facilitates the setup and use of microsatellite markers. In particular, the results of the "EcoMicro" project carried out by a large consortium of European teams will be presented. This project proposed a revised isolation method based on the 454 GS-FLX Titanium pyrosequencing of microsatellite-enriched DNA libraries. This procedure, that has been tested on >100 species, makes microsatellites more and more accessible to entomologists. New developments of genotyping methods based on Next-Generation sequencing are also expected to increase the cost-efficiency and informativeness of microsatellite markers.

Genetic structure of the mealybug *Pseudococcus viburni* (Hemiptera: Pseudococcidae) populations worldwide.

Margarita Correa[1], Eric Lombaert[2], Tania Zaviezo[3], Thibaut Malausa[4]

[1]Facultad de Agronomia e Ingenieria Forestal, Pontificia Universidad Catolica de Chile, Chile, [2]UMR ISA (INRA,UNSA,CNRS), France, [3]Facultad de Agronomia e Ingenieria Forestal, Pontificia Universidad Catolica de Chile, Chile, [4]UMR ISA (INRA,UNSA,CNRS), France

Pseudococcus viburni is a mealybug pest species attacking more than 46 families of plants, including important agricultural crops, worldwide. This widely spread species also displays remarkable morphological variations at diagnosis characters and DNA variations at nuclear and mitochondrial genes, suggesting the presence of differentiated population clusters. Here we used microsatellite markers to investigate the genetic structure of P. viburni populations worldwide. Microsatellite markers were developed from a pyrosequenced microsatellite-enriched DNA library. Twenty two multiplexed markers were then used to genotype twenty populations with different geographical origins. Population clustering analyses and genetic differentiation estimates were computed from the data. The results reveal low genetic variability within populations (heterozygosity rates ranging from 0.127 to 0.438 and an average number of alleles per population ranging from 0.739 to 5.826). They also reveal high Fst values between populations, ranging from 0 to 0.679 (mean Fst of 0.35). Clustering analyses suggest the occurrence of two population groups, one composed of South American populations, the other composed of other populations, while a population from New Zealand displays individuals from the two groups. Based on these results and those obtained with mitochondrial and nuclear ribosomal DNA, we discuss the factors impacting the population genetic structure.

Sex determination genes and *Wolbachia* in Queensland fruit fly, *Bactrocera tryoni*

Jennifer Morrow[1], Deborah Shearman[2], Marianne Frommer[3], Markus Riegler[4]

[1]University of Western Sydney, Australia, [2]University of New South Wales, Australia, [3]University of New South Wales, Australia, [4]University of Western Sydney, Australia

Bactrocera tryoni (Froggatt) (Diptera: Tephritidae) is Australia's most destructive horticultural pest. Suppression methods, including the release of irradiated, sterile individuals or individuals infected by Wolbachia (α-Proteobacteria), are techniques that will become increasingly useful with the introduction of a male-only strain. Wolbachia are intracellular bacteria of insects that can cause crossing incompatibilities and may interfere with genes involved in sex determination. To ultimately achieve a male-only strain of B. tryoni, a thorough understanding of the genes that form the sex determination pathway is necessary. The pathway has been well studied in Drosophila melanogaster (Meigen) (Diptera: Drosophilidae), and this has provided a starting point for characterising genes involved in sex determination in other Diptera. However, the initial signal in male Bactrocera is communicated by the Y-located dominant male determiner, M, which is absent in Drosophila species. The mode of action of M, and its direct targets have yet to be characterised in fruit flies or in any other Y-determined insect. A Y chromosome marker carried in a B.tryoni line can distinguish male and female embryos with a simple PCR assay, permitting the use of quantitative PCR to study expression of important sex-determination genes in sexed single embryos. This has helped to clarify the timing of M, and will enable transcriptome sequencing of separated male and female embryos at targeted developmental times.

Clearance of an errantivirus sequence in the production process of trivalent recombinant hemagglutinin (rHA) influenza vaccine, FluBlok®

Yoshifumi Hashimoto[1], Kathryn A. Rizzo[2]

[1]*Protein Sciences Corporation, U.S.A.*, [2]*Protein Sciences Corporation, U.S.A.*

Errantivirus is a group of invertebrate retroviruses, including an exogenous virus and LTR-retrotransposon based on ICTV classification. Dm gypsy virus is the only identified exogenous errantivirus. Exogenous errantiviruses have not been reported in lepidopteran insect cells, which are extensively used in recombinant protein production in the biotechnology and pharmaceutical industry. However, a low level of reverse transcriptase (RT) activity has been reported for lepidopteran cell substrates, raising questions whether this activity might particle-associated. Recently, a 240bp sequence similar to conserved domain of pol gene of errantivirus was cloned from genomic DNA in Sf9 and High5 cells. We also identified and cloned a 240bp sequence, Sf-37, from genomic DNA of our expresSF+® (SF+) cells and confirmed expression by RT-PCR analyses. We developed an RT-PCR for in process sample testing and an even more sensitive nested PCR method to address concerns of whether this Sf-37 sequence is present in our drug product, FluBlok®. We used a RT-PCR method to screen for the presence of Sf-37 RNA signal at various stages in the purification process and demonstrated that the Sf-37 RNA sequence is removed during the early up-stream purification process of our drug product. FluBlok® vaccine was concentrated by ultracentrifugation, and subsequently tested in the RT-PCR follow by the nested PCR. The nested PCR method that can detect a single copy of RNA was used for drug product testing. We confirmed that the Sf-37 RNA sequence cannot be detected in three doses of FluBlok®. This work was funded in part under contract HHSO100200900106C.

Growth performance evaluation and productivity of *Bombyx mori*(L) (Silkworm) fed with three varieties of *Morus alba*(L) mulberry plant

Folake Rachael Ogunleye[1], Oluwaseun Dorcas Popoola[2]
[1]*Ekiti State University, Nigeria,* [2]*Ekiti State University, Nigeria*

Ogunleye, R.F. and Popoola, D. O Department of Zoology, Ekiti State University, Ado Ekiti E-Mail: droluwaleye@yahoo.com Seunpop34@yahoo.com ABSTRACT The research work was carried out to evaluate and compare the growth performance and productivity of a strain of silkworm, Bombyx mori (EC1) fed with three different varieties of mulberry plant (K2, S-36 and E-Lobe).The experiment was carried out at ambient conditions 37oC and 55% R.H. The parameters used to evaluate the growth performance were larval length, width and weight while the characters used for productivity include shell weight, cocoon weight, shell ratio , filament weight , length, denir and number of breaks. The result revealed that the performance of mulberry leaves varied from each other and that silkworms fed with S-36 variety performed significantly higher in terms of growth and productivity. The next variety to it is the K2 and followed by E-lobe variety.

Ultrastructure of the antennal sensory organs of two *Fannia* species

Yi-Ou Chen[1], Ming Zhang[2], Xian-Hui Liu[3], Yan-Zhi Yang[4], Qi-ke Wang[5], Dong Zhang[6]

[1]Beijing Forestry University, China, [2]Beijing Forestry University, China, [3]Beijing Forestry University, China, [4]Beijing Forestry University, China, [5]Beijing Forestry University, China, [6]Beijing Forestry University, China

Fannia (Muscoidea: Fanniidae) species are the most important mechanical vectors of faecal-borne pathogens, larvae of them can cause intestinal and genital myiasis in men or domestic animals. Currently, there is a paucity of morphological information on antennal sensory organs of Fannia. To fill in the gap, we investigated the ultrastructure of antennal sensilla in two ubiquitous Fannia species (F. canicularis and F. scalaris) using scanning electron microscopy. Four distinct types of sensilla, including trichoid, basiconic, coeloconsa and clavate sensilla, and one type of olfactory pit are recorded in F. canicularis and F. scalaris. A cross-sectional view of the funiculus shows it to be triangular, with an anterodorsal surface, a dorsolateral margin and a posteroventral surface. The latter presents one large-size pit, containing basiconic sensilla, on median areas of the distal funiculus. Type, number, density and distribution of antennal sensilla and olfactory pit in Fannia species are compared with other muscoid flies : phytophagous anthomyiids and saprophagous muscids. According to the results above, the evolutionary trends and the function of antennal sensory organs are discussed in Muscoidea. Therefore, such studies would enrich the information about antennal sensilla of Fanniids, and contribute to the development of synthetic attractants for the monitoring and control of medical fly populations.

The molecular genetics of the oily (translucent) mutants in the silkworm, *Bombyx mori*

Lingyan Wang[1], Takashi Kiuchi[2], Yutaka Banno[3], Muwang Li[4], Susumu Katsuma[5], Toru Shimada[6]

[1]The University of Tokyo, Japan, [2]The University of Tokyo, Japan, [3]Kyushu University, Japan, [4]The University of Tokyo, Japan, [5]The University of Tokyo, Japan, [6]The University of Tokyo, Japan

Uric acid is the end product of nitrogen excretion in insects. It is also accumulated in tissues and organs such as fat body, epidermis and wing. The silkworm, Bombyx mori, is a typical insect accumulating uric acid in the body, and regarded as a model insect for the study on uric acid metabolism in insects. Uric acid is accumulated as urate granules in the epidermis of the silkworm, which makes the larval skin color white and non-translucent. More than 35 'oily' mutants of the silkworm show the translucent larval skin due to the absence and insufficiency of urate granules, and accordingly their larval skin color is more or less translucent. The genes controlling the oily phenotypes are dispersed among different loci on various chromosomes. Recently, some of them have been identified at the nucleotide sequence level. The oq and og mutants have the highly translucent larval skin due to the lack of xanthine dehydrogenase activity. The ow and od mutants are caused by the mutations of the genes encoding the proteins required for intracellular membrane traffic. The w-3 and os mutants are caused by the deficiencies of membrane transporter proteins. In our study, we found that the repression of dysbindin in the ov mutant possibly causes the translucent skin. The ok mutant is resulted from the abnormality of an ABC transporter. The study on oily mutants would improve our understanding of uric acid metabolism in insects and other organisms.

Assembly of empty Israeli acute paralysis virus capsids in baculovirus infected insect cells

Ian Jones[1], Abigail Cone[2], Junyuan Ren[3]

[1]University of Reading, United Kingdom, [2]University of Reading, United Kingdom, [3]University of Reading, United Kingdom

The dicistrovirus Israeli Acute Paralysis Virus (IAPV) has been implicated in the worldwide honey bee decline linked to colony collapse disorder (CCD). Studies of the virus in pure culture would be valuable but are restricted by available isolates and permissive cell culture. Here we show that coupling the IAPV major structural precursor protein ORF2 to its cognate 3C-like processing enzyme results in processing of the precursor to the individual structural proteins following expression by a recombinant baculovirus in a number of insect cell lines and that the efficiency of expression is influenced by the level of 3C protein. The mature IAPV structural proteins assembled into empty capsids that were identified by their sedimentation profile in sucrose velocity gradients and peak fractions showed typical dicistrovirus like particles when examined by electron microscopy. Capsids reacted strongly with a polyvalent serum generated to a fragment of ORF2 expressed in bacteria suggesting the feasibility of a simple diagnostic for the presence of IAPV infection. Recombinant IAPV capsids may be useful for on-going investigation of the causes of CCD and similar expression technology may allow defined reagents to be generated for many other bee viruses within the picornavirus family.

Olfaction in a vector fruitfly *Phortica variegata*

Siju Kunhi Purayil[1], Domenico Otranto[2], Riccardo P. Lia[3], Ilona C. Grunwald Kadow[4]

[1]Max Planck Institute of Neurobiology, Germany, [2]Faculty of Veterinary Medicine, University of Bari, Italy, [3]Faculty of Veterinary Medicine, University of Bari, Italy, [4]Max Planck Institute of Neurobiology, Germany

The primitive fruitfly, Phortica variegata belonging to the family of Drosophilidae and to the Steganinae subfamily, shows a peculiar and rather unusual zoophilic behavior unlike other fruitflies of the same family. Apart from feeding on fruits, P. variegata flies also feed on lachrymal secretions of animals and humans thus transmitting Thelazia callipaeda (Spirurida, Thelazidae) eyeworms that causes thelaziosis, potentially leading to blindness. What contributes to this special zoophilic behavior in these flies remains unknown. Since olfaction plays an important role in the life of other pathogen transmitting vector insects, we investigated the olfactory system of these flies to understand its role in their distinct zoophilic behavior. In this study, for the first time, we describe the olfactory system of a vector fruitfly. We show that P. variegata flies have well-developed olfactory system similar to their well-known counterpart Drosophila melanogaster. In P. variegata, the peripheral olfactory organs, the antenna and maxillary palp, harbor distinct types of olfactory sensilla. The primary olfactory center in the brain, the antennal lobes, shows a glomerular organization and receives neuronal input from the peripheral olfactory organs in an organotopic pattern. Further, using electrophysiological methods we demonstrate the ability of these flies to detect both fruit related and animal related odors. These results allow us to compare and discuss the olfactory system of P. variegata with that of the well described D. melanogaster olfactory system.

Sexual conflict among the lichen tuft moths.

Rebecca Bennik
The University of Auckland, New Zealand

Insect species display extraordinary variation in male genital morphology; therefore genital evolution is rapid and divergent. Previous assumptions for diversification in genital morphology were based on species isolation and pleiotropy, but subsequent comparative research has failed to support these hypotheses. Recent comparative and experimental research has proposed sexual selection to be the most likely driver of rapid and divergent evolution of genitalia, either via sperm competition, cryptic female choice, or sexual conflict. Sexual conflict may drive genital evolution through opposing selection of male and female reproductive strategies as genital adaptations that allow males a competitive advantage may consequently reduce female fitness leading to an evolutionary arms race via sexually antagonistic co-evolution (SAC). Lichen tuft moths of the genus Izatha (Lepidoptera: Oecophoridae) are excellent candidates for exploring the potential for sexual conflict to drive genital evolution, as some males have detachable spines (deciduous cornuti) which are ejected into the female reproductive tract during their first mating, apparently causing damage. Some species lack deciduous cornuti, but have permanently attached sclerotised teeth on the phallus, whilst others lack these structures all together. Here I present a molecular and morphological phylogenetic analysis of the genus that provides insight into the evolution of these complex genitalic adaptations. Genital complexity appears to have evolved along multiple paths, via the modification of different genital structures. Izatha therefore may represent an ideal model for the study of genital evolution.

Interactions between native insects and Australian invasive acacias in Europe

Paiva Maria-Rosa[1], Silva Pedro Ribeiro[2], Ruas Sara[3]

[1]*Universidade Nova de Lisboa and Universidade Tecnica de Lisboa, Portugal,* [2]*Universidade Nova de Lisboa, Portugal,* [3]*Universidade Nova de Lisboa, Portugal*

Over 20 species of Australian acacias have been introduced in Europe, most of which became invasive and threaten the sustainability of native ecosystems. However, interactions between exotic acacias and the native entomofauna remain largely unstudied. Further, the role of exotic introduced insects involved in links of the food webs of native ecosystems, is also unknown. Research was conducted in Portugal, on Acacia longifolia and Acacia saligna, two of the most problematic invasive arboreal species in southern Europe. The composition of the communities of potential insect pollinators, associated with the acacias, was studied and comparisons made between the flowering and post-flowering periods. Although significantly more Hymenoptera and Coleoptera were caught when inflorescences were present, thus indicating that generalist pollinators likely promote seed production, their contribution to the invasive potential of A. longifolia should remain low. The role of ants in the dispersal of A. saligna seeds was also investigated. It was concluded that some common native ant species, particularly Aphaenogaster senilis and Messor barbarus, are efficient seed dispersers and promote the establishment of seed banks. Since acacia seeds may remain viable for decades, granivorous ants likely play an important role in their establishment and spread. By contrast, the exotic Argentine ant, Linepithema humile, that has invaded the coastal areas of Portugal, consumes the eliosomes of A. saligna seeds but do not translocate them, thus decreasing their fitness. Findings are innovative and uncover mutualistic relationships, presently evolving between native insects and exotic plants, which result in an adaptative advantage for the invaders.

Enhancement of fruit quality in green pepper through pollination by *Hypotrigona gribodoi* in small scale farms in western Kenya

Kiatoko Nkoba[1], Suresh Kumar Raina[2], Elliud Muli[3], Jones Mueke[4]

[1]International Centre for Insect Physiology and Ecology (icipe), Kenya, [2]International Centre for Insect Physiology and Ecology (icipe), Kenya, [3]South Eastern University College (A Constituent College of the University of Nairobi), Kenya, [4]Kenyatta University, Kenya

A study was carried out in Kakamega forest, western region of Kenya, to evaluate the effectiveness of the stingless bee Hypotrigona gribodoi Magretti on pollination of green pepper (Capsicum annuum L.). Three treatments were applied and consisted of self-pollination, pollination by feral pollinators in open field and pollination by H. gribodoi in net cage. The difference of yield in fruits and seeds quality was compare among the treatments. Plants whose flowers were pollinated by H. gribodoi produced heavier fruits with a higher number of seeds compared to self-pollinated flowers or flowers pollinated by feral insects. Moreover, seeds were significantly bigger in size in fruits resulting from flowers pollinated by H. gribodoi compared to fruits obtained from self-pollinated flowers or flowers pollinated by feral insects. We therefore conclude that H. gribodoi is an efficient pollinator of green pepper in tropical region of East Africa.

Research and utilization of Chinese gall aphids (Hemiptera: Aphididae: Fordini) in China

Zixiang Yang[1], Xiaoming Chen[2], Ying Feng[3], Ping Liu[4]

[1]Chinese academy of forestry, China, [2]Chinese academy of forestry, China, [3]Chinese academy of forestry, China, [4]Chinese academy of forestry, China

Chinese gall aphids are a small group among the gall-inducing aphids. They include six genera, ten species, and four subspecies which have complex life cycles with cyclical parthenogenesis and multiple generations with alternative hosts. Their life cycle includes sexual and asexual reproduction, and alternation between the primary hosts (Anacardiaceae: Rhus) and certain secondary hosts (mosses). Three primary host plants and more than fifty secondary host mosses have been reported in China. Each gall aphid species or subspecies form a characteritic, species-specific gall on its primary host. The galls, which called Chinese gallnuts (Wubeizi), are sealed and sac-like which show great variation in shape, size, structure, and galling-site. Generally, each gall is initiated by a single fundatrix which reproduces parthenogenetically for three generations within a gall and the apterous fundatrigeniae live in it for about three to five months. The most prominent species is Schlechtendalia chinensis, which forms horned-like galls on Rhus chinensis. The gallnuts have been mainly used for medicine and chemical purposes for more than two thousand years because they are comprised mainly of tannins. They are still important traditional resources and commercial exports in China until now. The annual yield of gallnuts in China is 5-6 million kilograms and about 95% of the total world yield. Many efforts have been made to study the artifical breeding techniques of aphid in order to increase the yield. It is a main income source for the farmers who rear and utilize the gallnuts in Southwest China.

Evolution and biogeography of *Bombyx mandarina* compared with the domesticated mori revealed by Bayesian inference of DNA sequences data from some transposons including mariner-like elements (MLEs)

Yumiko Nakajima[1], Shigeki Nakagome[2], Shuhei Mano[3]

[1]University of the Ryukyus, Japan, [2]The Institute of Statistical Mathematics, Japan, [3]The Institute of Statistical Mathematics, Japan

Ancestral inferences based on polymorphism data have been great interests in biogeographical studies using natural populations. And for taking advantage of the transposons including mariner-like elements (MLEs) as an evolutionary clock, reliable estimation for the time of each event is required. In this presentation, we demonstrate our coalescent approach is useful tool to estimate times of evolutionary events within a species and the ancient mariner-like element (MLE) sequences can be applied as a molecular marker to understand geographical relationships among distantly related species. "BmTNML" locus is composed of three different transposons (Bmmar2 type of MLE, L1Bm and BMC1 retrotransposable elements) in almost all the mori strains (Nakajima et al., J. Mol. Evol., 1999). And it is recently cleared that this unit exists only one copy on the Chromosome 6 of B. mori. But the transposons insertion patterns in this locus of mandarina are very different from those of mori. Based on the genealogy defined by insertions/deletions of the transposons in this locus, we estimated the most common recent ancestors (TMRCAs) and ages of these events by using the 45 sequences of the TEs and host genome from mori and mandarina. These results suggested the neutrality of the MLE insertion in the B. mandarina population and the MLE inserted into the common ancestor's genome of mori and mandarina. It was also strongly supported that the new discovered maT type of TEs insertion and the omission event in this locus might be occurred very recently only in the restricted population of mandarina.

Queen selection in three genera of social wasps of tribe Epiponini (Vespidae: Polistinae)

Laura Chavarria[1], Fernando Noll[2]

[1]Universidade de Sao Paulo, Brazil, [2]Universidade Estadual Paulista, Brazil

Queen selection is a very complex process, and it is poorly studied in most of species of neotropical swarm-founding wasps. Queen selection was described in detail only for Metapolybia aztecoides. Since then, few studies were performed to understand how queens are selected. Queen selection could vary between species because there is a lot of variation across the tribe. For this reason, we studied queen selection process in three genera of Epiponini in different stages of colony cycle. Two colonies of Metapolybia, Chartergellus and one of Protopolybia were observed in Brazil and Costa Rica. To identify queens, eggs were removed from cells to stimulate oviposition. Egg-laying females were marked. Queen behavior and their interactions were observed. When colonies were not in a queen selection stage, queen removal tests were performed to stimulate new queens production and to observe behavioral responses in orphan colonies. There was an increase in the amount of display behaviors during queen's selection stage. After queen elimination, the amount of egg-laying females increased, mainly in Metapolybia and Chartergellus. In most colonies new queens were old females with less developed ovaries. Our results showed that females from these social wasps are reproductive plastic, that even old females could develop their ovaries in the absence of queens. In consequence, workers can recognize and respond to queens' absence. Also, we show important differences in queen selection process between genera, which also could be related to colony cycle.

ButterflyIndia: Cyber community initiative to document Indian butterflies

Vijay Vasant Barve[1], Amol Prabhakar Patwardhan[2], Arjan Basuroy[3]

[1]University of Kansas, U.S.A., [2]K. J. Somaiya College of Science and Commerce, Mumbai, India, [3]Nature Mates, Kolkata, India

Internet has become integral part of our daily life in past few years and is changing many of the things we do on day to day basis. Biodiversity documentation and citizen science are positively impacted too. Here we present a case study of a cyber-community of Indian Butterfly lovers and how it is harnessing the internet in its operations. Initiated in 2001 with mere 25 members, it has grown to more than 1450 member and has exchanged more than 25000 messages. The group has organised 12 meets which are a combination of field-trips and mini-conferences. The group has contributed to numerous books, publications and websites documenting butterfly diversity of Indian subcontinent. There have been several discoveries of rare and very rare butterflies by citizen scientists and confirmations by experts through the e-group. The whole group works on no profit no loss basis.

Progress of eriophyoid mite research in China (Acari: Eriophyoidea)

Xiao-Feng Xue[1], Xiao-Yue Hong[2]
[1]*Nanjing Agricultural University, China,* [2]*Nanjing Agricultural University, China*

The eriophyoid mites, unlike other Acari, have only two pairs of legs. Body fusiform or vermiform in shape, white or light yellow in color, usually 200μm in length and 70μm in width. Normally, eriophyoid mites cannot be found by naked eyes. Eriophyoid mites are obligate plant feeders with strong host specificity. Some species have great economic importance in agriculture, such as Aculops lycopersici (Tryon, 1917) infesting Tomato, Phyllocoptruta oleivora (Ashmead, 1879) infesting Citrus sp. (Rutaceae), Aceria tosichella Keifer, 1969 infesting Wheat and Barley and can transmit virus (WSMV). Up to 2011, there are three families, 357 genera and 4,404 species reported in the world. Up to 2010, 932 species belonging to 3 families and 187 genera are reported in China. The taxonomy of eriophyoid mites in mainland China has developed rapidly in recent years. Trotter (1900) is the first person describing new eriophyoid mites collected in China. He reported two new species. Hai-Yuan Kuang (1980) is the first Chinese who conducted taxonomic research of the Eriophyoidea in mainland China. During 1980 to 2005, Kuang and his co-authors described 244 new species from China. Xiao-Yue Hong and his co-authors described 232 new species from China, and most of the species were described from 2005 to 2009. Sui-Gai Wei and his co-authors described 122 new species from Guangxi Zhuang Autonomous Region in China. Kun-Wei Huang and his co-authors described 229 new species from Taiwan. Biology and control of eriophyoid mites have been focused only on a few species.

Undergraduates gain experiential learning experience through unique pollination biology research program

Sujaya Rao[1], Sandra DeBano[2], Andrew Moldenke[3]

[1]Oregon State University, U.S.A., [2]Oregon State University, U.S.A., [3]Oregon State University, U.S.A.

Research opportunities provide undergraduate students with valuable experiential learning experiences that enhance their degree programs, and enable them to be competitive for graduate school admission and in the job market. In particular, focused research training provided to a cohort of students on a topic of current relevance enables training of a new generation of scientists with the ability to address global issues. However, universities offer little, if any, support for development of such programs. At Oregon State University, we hosted a National Science Foundation supported REU (Research Experiences for Undergraduates) Site program that trained undergraduates in comparative, multidisciplinary research in pollination biology over 10 weeks in the summer. Students were recruited nationwide, and provided background information on bees, plants, ecology, conservation, sampling and statistical analyses. They examined plant-pollinator interactions while rotating through three ecologically distinct sites across Oregon for experience with both fundamental and applied approaches to pollination research. Initially, they helped with existing projects at all three sites. Subsequently, they conducted independent research on a specific topic and presented their results during a Pollination Conference. Program outcomes assessed through pre and post quizzes indicate enhanced knowledge about entomology, research methodology, and conservation issues. Feedback received 1-2 years later indicated that the program motivated alumni to seek opportunities to present and publish their REU experiences, to conduct senior thesis research related to bees and pollination, seek additional research experiences, and to enroll in graduate programs. The program also enabled them to receive highly competitive fellowships for national and international research.

Biorational control of kaydid pests on oil palms in Papua New Guinea

Genet M. Tulgetske[1], Thomas A. Miller[2]

[1]University of California, Riverside, U.S.A., [2]University of California, Riverside, U.S.A.

More than 80% of the reports of pest problems in Papua New Guinea each year derive from the Sexava group of katydids (Tettigoniidae). Current control relies on chemical treatment using methamidophos, which is unsustainable due to the high cost, its failure to significantly reduce loss, and the impending discontinuation of supply. We are investigating an alternative pest control approach using a fungal delivery system for insecticidal proteins to rapidly and effectively control katydid pests. In this study, isolates of the entomopathogenic fungus, Metarhizium anisopliae, were identified as potential biopesticide candidates to control katydid pests on oil palm crops in PNG. Tests were performed in the laboratory using a range of fungal concentrations on several insect species to determine the infectivity of the fungal isolates to long-horn grasshoppers and the specificity of the candidate fungal biopesticides. Since rapid mortality is needed to effectively control katydid damage, the results of this study will identify a fungal isolate(s) to be genetically engineered to express insecticidal peptides from scorpion or spider venoms. This will increase the virulence of the biopesticide agent, reducing the required spore dose and time of treatment.

Prevention of incursion of coffee berry borer (*Hypothenemus hampei*) into Papua New Guinea and implementation of national surveillance scheme.

Bryony Taylor[1], Sean T Murphy[2]

[1]CABI Europe-UK, United Kingdom, [2]CABI Europe-UK, United Kingdom

Coffee Berry Borer (Hypothenemus hampei) (CBB) originates in Africa and has spread to the coffee growing regions of the world causing severe damage to coffee and affecting smallholder livelihoods. CBB bores into the distal end of cherries and produces progeny which form 'galleries' in the bean and this can frequently cause up to 80% crop yield loss. The spread of CBB is facilitated through movement of coffee cherries and gunny bags. In 2008, CBB was recorded 50km from the border of CBB-free Papua New Guinea, in Oksibil, Indonesia, threatening the livelihoods of PNG coffee farmers. Almost 50% of rural households in PNG are involved with the coffee industry. To pre-empt potential effect on livelihoods, a project investigating the prevention of incursion of CBB into PNG and to monitor potential pathways of entry and spread into and within the country was initiated. This ACIAR funded project (a collaboration between CABI, Coffee Industry Corporation of PNG and NAQIA - National Agricultural Quarantine Inspection Authority) aimed to train officials to recognise signs and symptoms of infestation, assess the movement of coffee (at the farm level and through trade), and to establish a national surveillance scheme to monitor for the pest internally to facilitate early detection. The work identified the importance of several potential vectors and pathways of movement for CBB, highlighting the risk of incursion and movement of CBB. An overview of the analysis of vectors and pathways and the surveillance methodology is presented.

Efficient production of knockout crickets using ZFNs and TALENs

Takahito Watanabe[1], Hiroshi Ochiai[2], Tetsushi Sakuma[3], Taro Nakamura[4], Taro Mito[5], Takashi Yamamoto[6], Sumihare Noji[7]

[1]The University of Tokushima, Japan, [2]Hiroshima University, Japan, [3]Hiroshima University, Japan, [4]The University of Tokushima, Japan, [5]The University of Tokushima, Japan, [6]Hiroshima University, Japan, [7]The University of Tokushima, Japan

An orthopteran insect, the cricket Gryllus bimaculatus, has recently become a hemimetabolous insect model system, whereas target mutagenesis was intractable in this species as in other non-Drosophila systems. Here we use custom designed nucleases technology, zinc-finger nuclease (ZFN) and transcription activator-like effector nuclease (TALEN), in cricket embryos to introduce sequence-specific mutation via nonhomologous end joining (NHEJ)-mediated deletions or insertions at the target site. To examine the potential of custom designed nucleases in the cricket, we designed a ZFN pair for EGFP, and microinjected mRNA into fertilized eggs expressing EGFP in the cytoplasm. As a result, we obtained germ-line mutant crickets at the high rate (48%). Next, we attempted to induce mutations into an endogenous gene Gb'laccase2, which has been shown to be involved in cuticle tanning. We designed a ZFN and TALEN pair for Gb'laccase2, and microinjected mRNA of these nucleases into wild-type fertilized eggs. Spots of tanning defects were observed in nuclease-treated G0 nymphs, indicating somatic mutations were induced by ZFNs and TALENs. 47% (ZFNs) and 17% (TALENs) of founder animals transmitted disrupted gene alleles. Via selection of G1 heterozygotes by mutation detection assays and subsequent sibling crosses, we obtained homozygous targeted alleles exhibiting expected cuticle-tanning-defective phenotypes. Our approach depends neither on the particular mutant phenotype nor genetic tractability of the organism. It should be generally applicable to any genomic locus in organisms that allow mRNA delivery into the embryo. Thus, our results should facilitate the direct genomic manipulation of non-model organisms and their analysis by functional genomics.

The change of fauna and soil characteristics for Saemankeum reclaimed region in Korea

Hong-Yul Seo[1], Ki-Kyung Kim[2]

[1]National Institute of Biological Resourses, Republic of Korea, [2]National Institute of Biological Resourses, Republic of Korea

Saemankeum is the largest region, changed into reclaimed region in Korea, recently. The first purpose of Saemankeum reclaimed region is the development of new farmland. Since 2006, the construction of embankment, Saemankeum region has been isolated from the sea, slowly dried and changed into the land. The soil animal are very important for the formation of agricultural soil and also represent a large portion of the healthiness of agricultural soil. The soil animal carry out a wide range of ecosystem process that are essential crop production, soil resource quality and environmental health. In order to examine the change of reclaimed region related with the formation of new farmland, we examined the soil chemical properties and the emergence of the soil mesofauna in Saemankeum reclaimed region in 2006, 2011, separately. We investigated three locations in Saemankeun in pedological parameters - pH, organic matter, P2O5, SiO2, EC, T-N, Ex. Cation and CEC. Also, soil mesofauna groups, such as Diplura, Homoptera, Coleoptera, Dilptera, Lepidoptera, Hymenoptera, Collembola, Acari, Annelida, etc, have been examined. We analyzed the change of soil quality and the emergence of soil animals in newly formed Saemankeum reclaimed land in Korea.

The role of urban wastewater farms as a common denominator for malaria and diarrhoeal disease transmission

Razak Seidu[1], Amina Abubakari[2], Robert Clement Abaidoo[3], Hans Overgaard[4], Thor Axel Stenstrom[5]

[1]Norwegian University of Life Sciences, Norway, [2]Norwegian University of Life Sciences, Norway, [3]Kwame Nkrumah University of Science and Technology, Ghana, [4]Norwegian University of Life Sciences, Norway, [5]Norwegian University of Life Sciences, Norway

Worldwide, wastewater use in urban agriculture is increasing at a rapid pace due to rapid urbanization and its accompanying stress on limited freshwater resources. The economic and food security benefits associated with wastewater use in urban agriculture are enormous, but so also are the public health burden it exacts on the urban population. Wastewater use in agriculture has been implicated for the transmission of diarrhoeal diseases among farmers and their family members using wastewater and consumers of the wastewater farm products. Malaria mosquitoes also breed in wastewater farms, thus exposing urban populations living in close proximity to these farms to increased malaria risk. The problem of malaria is further exacerbated by the use of agro-chemicals on the wastewater farms that make malaria mosquitoes more resistant. So far, little is known of the role of wastewater farms for the combined risk of diarrhea and malaria. An understanding of this role would be important for developing integrated interventions. The main aim of this study is to assess the role of urban wastewater farms as a common denominator for the transmission of malaria and diarrhoeal disease in urban Ghana. The study is being conducted in Kumasi, the second largest city in Ghana, where more than 12000 hectares of urban vegetable farms are irrigated with wastewater. The outcome of the study will lead to the development of integrated interventions for mitigating malaria and diarrhoeal disease transmission associated with wastewater irrigation.

Madagascar's millipede assassin bugs (Hemiptera: Reduviidae: Ectrichodiinae): taxonomy, phylogenetics, and sexual dimorphism

Michael Forthman[1], Christiane Weirauch[2]

[1]*University of California - Riverside, U.S.A.*, [2]*University of California - Riverside, U.S.A.*

Millipede assassin bugs in the subfamily Ectrichodiinae (Hemiptera: Reduviidae) are a diverse group (>600 species) of specialized millipede predators, with only 9 species documented from Madagascar, one of the world's premier biodiversity hotspots of critical conservation priority. The California Academy of Sciences' Terrestrial Arthropod Inventory of Madagascar Project has been established to address the need for taxonomic exploration of Malagasy arthropods and has provided a unique opportunity to examine >1,400 specimens of ectrichodiines and explore delimitation of new taxa based on male specimens. After examining 90 external morphological and genitalic characters, it is apparent that the Malagasy ectrichodiine fauna comprises more than 40 species, many of which represent new species. Ectrichodiinae are unusual among Reduviidae in that species frequently display strong sexual dimorphism, rendering association of males and females difficult. To associate females with males, an uncorrected pairwise distance analysis using ~430 bp of partial mitochondrial cytochrome c oxidase subunit I DNA sequences were analyzed, unambiguously matching some females to males. The first molecular dataset (COI, 28S D2-D3 rDNA; 60 taxa) of Ectrichodiinae was assembled to test generic concepts, as well as to assess the monophyly of Malagasy ectrichodiines. Results show that phylogenetics is an important tool to inform decision-making in taxonomy and that a small amount of sequence data can impact our ability to match dimorphic sexes in Reduviidae.

Phylogenetic reconstruction of the *Papilio memnon* complex suggests multiple origins of mimetic colour pattern and sexual dimorphism

Chia-Hsuan Wei[1], Matheiu Joron[2], Shen-Horn Yen[3]

[1]National Sun Yat-Sen University, Taiwan, [2]France, [3]National Sun Yat-Sen University, Taiwan

Mimicry refers to profitable/unprofitable organism benefiting from sharing conspicuous signals with unprofitable species. The evolutionary origin of mimetic characters is still a complicated mystery, especially when polymorphism and sexually dimorphism are involved. Papilio memnon, which the females exhibit at least 17 polymorphic forms, was considered as mimics of Troidini swallowtail butterflies and has been regarded as classical textbook case of Batesian mimicry. Having examined a long series of the museum material and observed field populations from different geographical areas, however, we found that most female forms of P. memnon do not seem to be involved in any mimicry ring. This may imply that female-limited polymorphism is not necessarily correlated with mimicry. To investigate whether the mimetic characters evolve from a single origin and whether the characters contributing to mimicry have correlated evolution, we reconstructed the Bayesian phylogeny of most of the species assigned to the species group and other species of the subgenus Melelaides, and a maximum likelihood model was used to trace the evolutionary history of 3 major character groups. The results show that: (1) P. memnon complex may be not a monophyletic because P. polymnestor is clustered within the clade; (2) no directional evolutionary trend from imperfect to accurate mimicry is observed; (3) the red basal patch on forewing underside occurs twice independently in P. memnon and P. thaiwanus; and (4) the mimicry associated with a specific pattern is area-dependent. Occurrence of a large number of non-mimetic female forms requires interpretation of other hypothesis, e.g. male mate-mate selection.

The evolution of host utilization and shelter building behavior in the genus *Parapoynx* (Lepidoptera: Crambidae: Acentropinae)

Ling-Ying Tsai[1], Chia-Hsuan Wei[2], Shen-Horn Yen[3]

[1]National Sun Yat-Sen University, Kaohsiung, Taiwan, [2]National Sun Yat-Sen University, Kaohsiung, Taiwan, [3]National Sun Yat-Sen University, Kaohsiung, Taiwan

The genus Parapoynx is a medium-sized crambid group with a global distribution except for Antarctica. The caterpillars are truly aquatic, bearing branched tracheal gills and making portable cases using hostplant leaves. Our rearing experience and host acceptance tests reveal that caterpillars of different species-groups associate with aquatic plants of specific growing forms rather with closer phylogenetic affinities. This phenomenon is remarkable because most studies focusing on evolutionary trend between generalist and specialist herbivores specify on host association tied with plant's taxonomy, while this case suggests that ecological need is much more important in term of shaping host specificity. The present study aims to test two hypotheses: (1) If Agassiziella or Elophila is the sistergroup of Parapoynx? (2) If there is any evolutionary pattern of hostplant utilization within the genus? If yes, does it correspond to geographical or phylogenetic constraint? We applied Bayesian inference to reconstruct a phylogenetic tree of selected Acentropinae genera and Schoenobiinae species as an outgroup using COI (695 bp) and Ef1-α (666 bp). We also used adult morphological characters from nearly all the recognized species-groups to reconstruct a phylogeny of the genus using Maximum Parsimony. Our results reject the hypothesis either Agassiziella or Elophila is the sistergroup of Parapoynx. Most of the sampled Parapoynx are confined to certain plant growing types. However, species utilizing the same plant growing form are not distributed in the same geographical region or having closer phylogenetic relationships. Our results also suggest that hostplant form may have shaped the case-making behavior of Parapoynx.

Phylogenetic analysis of the spider mite family Tetranychidae

Tomoko Matsuda[1], Norihide Hinomoto[2], Maiko Morishita[3], Yasuki Kitashima[4], Tetsuo Gotoh[5]

[1]Ibaraki University, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]Ibaraki University, Japan, [4]Ibaraki University, Japan, [5]Ibaraki University, Japan

The spider mite family Tetranychidae comprises about 1,200 species, including the most injurious plant-feeding mites, and represents one of the most cosmopolitan and economically important groups of terrestrial arthropods. As for many other organisms, molecular information of spider mites is increasingly used to answer taxonomic and systematic questions. The cytochrome c oxidase subunit I (COI) gene of mitochondrial DNA and the internal transcribed spacer (ITS) of nuclear ribosomal RNA (rRNA) gene are being used for species identification and phylogenetic reconstruction within the family Tetranychidae. Although COI and ITS regions are effective for species identification between closely related species, these sequences have not consistently resolved genus-level phylogenetic relationships. On the other hand, rRNA gene sequences may be more useful for higher-level phylogeny. Therefore, we determined sequences of 18S and 28S regions, of spider mite species belonging to the 15 tetranychid genera and examined their phylogenetic relationships. Some genera, such as Aponychus and Panonychus, appeared to be monophyletic. The phylogenetic tree based on 18S and 28S sequences separates the Oligonychus species into two clades (I and II), with the Tetranychus species included in clade II. Thus, Oligonychus and Tetranychus were not separated using 18S and 28S rRNA genes.

A pteromalid (Hymenoptera: Chalcidoidea) parasitizing larvae of *Aphidoletes aphidimyza* (Diptera: Cecidomyiidae) and the first finding of the facial pit in Chalcidoidea

Kazunori Matsuo[1], Junichiro Abe[2], Kanako Atomura[3], Junichi Yukawa[4]

[1]Kyushu University, Japan, [2]Lowland Crops Research Division, NARO Western Region Agricultural Research Center, Japan, [3]Faculty of Agriculture, Kinki University, Japan, [4]Entomological Laboratory, Faculty of Agriculture, Kyushu University, Japan

An endoparasitoid emerged from pupae of an aphidophagous cecidomyiid Aphidoletes aphidimyza in Japan. Examination of morphological features revealed that the endoparasitoid was identical to Gastrancistrus fuscicornis (Pteromalidae) that has been known from European countries. The host insect of G. fuscicornis was thought to be an unidentified aphid because three females in the Hartig's collection have been mounted with the skins of parasitized aphids on some rose leaves. However, no species of the genus have been reared from aphid mummies up to the present. This information supports the current result that G. fuscicornis is not an aphid parasitoid but larval-pupal parasitoid of A. aphidimyza. During the course of morphological observation, we found a pit on the head of male and female of G. fuscicornis. Examination of internal cuticular structure revealed that a bell shaped internal cuticular apodeme was connected to the pit but not to the tentorium. According to the definition of the non-tentrial pits, the pit found in G. fuscicornis corresponds to the facial pit. This is the first finding of the facial pit in Chalcidoidea.

Keywords:*Gastrancistrus fuscicornis, predacious gall midge, Japan.*

Population genetics of common Palearctic solitary bee *Anthophora plumipes* (Hymenoptera: Anthophoridae) in whole species areal and result of its recent introduction in the USA

Katerina Cerna[1], Pavel Munclinger[2], Jakub Straka[3]

[1]Faculty of Science, Charles University in Prague, Czech Republic, [2]Faculty of Science, Charles University in Prague, Czech Republic, [3]Faculty of Science, Charles University in Prague, Czech Republic

Anthophora plumipes (syn. A. pilipes) is a common polylectic early spring solitary bee, that nests in aggregations. The species is often synathropic and thus well known. It is spread across the whole Europe, North Africa, Middle East and East Asia (www.discoverlife.org). As a promising pollinator, A. plumipes was introduced to the USA in Maryland from Japan (Sugata-Cho, Matsue) in 1989. Originally, 109 diapausing adults were shipped from Japan from which 56 adults were used for the introduction. Bees were kept outdoors for five years and population approximately tripled each year (Batra, 1994). We have obtained material of A. plumipes from the eastern coast of the USA, where it is nowadays rather abundant, to perform the population-genetic analysis of this species, because with its known history it represents very interesting evolutionary model. We further collected population samples from the most parts of its areal range, which enabled us to perform complete population-genetic analyses of this species in the whole areal. We used several novel microsatellite loci developed for this purpose (Cerna & Straka, 2012) and also performed analysis on mitochondrial gene COI. Our results show interesting features concerning both populations genetic of this species as well as the estimation of success of presented introduction of A. plumipes to the USA. Literature cited: Batra S. (1994): Proc. Entomol. Soc. Wash. 96: 98-119. Cerna K. & Straka J. (2012): Eur. J. Entomol. 109:155-160.

Multiple nuclear and mitochondrial DNA analyses support a cryptic species complex of the global invasive pest, *Bemisia tabaci* (Gennadius) (Insecta: Hemiptera: Aleyrodidae)

Chia-Hung Hsieh[1], Hurng-Yi Wang[2], Cheng-Han Chung[3], Chun-Hung Chen[4], Chiun-Cheng Ko[5]

[1]National Taiwan University, Taiwan, [2]National Taiwan University, Taiwan, [3]National Taiwan University, Taiwan, [4]Council of Agriculture, Executive Yuan, Taiwan, [5]National Taiwan University, Taiwan

Cryptic species is an important issue to understand the biodiversity and evolutionary biology. Detection of the species status influences the conservation decision and invasive pest management. DNA sequences are powerful tools to discriminate morphologically indistinguishable species. Multiple nuclear and mitochondrial genes and multiple outgroups were used to detect the species status of the global invasive pest, Bemisia tabaci. Phylogenetic analyses revealed B. tabaci clustered with several Bemisia species and not a monophyletic group. The topologies indicated the paraphyletic origin and three phylogroups of B. tabaci. Intraspecies genetic divergent of B. tabaci was higher than interspecies of Bemisia species (Lipaleyrodes group). High genetic divergence between genetic groups of B. tabaci suggested at least each genetic group was a genetic species. Bayesian species delimitation detected the reproductive isolation between genetic groups of B. tabaci and supported each genetic group was a biological species. Isolation with migration model was used to estimate the gene flow and no significant gene flow was observed between closed related genetic groups of B. tabaci. Sympatric distribution of two different genetic groups of B. tabaci were observed in a poinsettia greenhouse, microsatellite analyses showed strong reproductive isolation between them and provided direct evidence to support a cryptic species complex. Combination of multiple loci was first used to infer the species status of B. tabaci and suggested a cryptic species complex based on genetic species concept and biological species concept. Cryptic species status is important to understand the cryptic biological invasion and help to formulate the invasive pest control.

Diverse neuropterans in the Mesozoic Ecosystems of Northeastern China

Yongjie Wang[1], Dong Ren[2]

[1]Capital Normal Unversity, China, [2]Capital Normal Unversity, China

Mesozoic Neuroptera shows most species richness and morphological diversity in the Northeastern China, suggested it should have been a golden time for neuropterans in Mesozoic Era. Up to date, 18 families, 42 genera and 56 species have been described in Mesozoic China, and mainly found in the Jiulongshan Formation and Yixian Formation. Based on morphological data, incorporating most fossil and extant families, the familial phylogenetic relationships of Neuroptera were re-constructed. Four extinct families, Permithonidae、Archeosmylidae、Mesithonidae and Nevrorthidae constitute the stem-groups of Neuroptera, representing the earliest division of Neuroptera. The suborder Myrmeleontiformia is confirmed, and Saucrosmylidae, Kalligrammatidae, Panfiloviidae, Aetheogrammatidae and Grammolingidae are assigned to the suborder. The superfamily Chrysopoidea is corroborated, comprising of Limaiidae、Tachinyphidae、Allopteridae、Mesochrysopidae and Chrysopidae. According to the fossil records of Neuroptera, it is inferred the familial division of Neuroptera is likely at the Middle Jurassic. The Mesozoic fossil lacewings exhibit some specialized co-evolution relationships with the contemporaneous plants and environments that have been lost in the Modern insects, etc. the oldest pinnate leaf-mimicking insects, Bellinympha filicifolia and B. dancei reveal a specialized co-evolution of insects and gymnosperms. Other extinct groups: Kalligrammatidae, Grammolingidae and Saucrosmylinae show some special traits that are different from the modern neuropterans, e.g. extremely large body size, peculiar wing marks and special behavioral adaptation. These enigmatic insects implied the diverse living strategies of Neuroptera before adaptation of angiosperms. The research of Mesozoic neuropterans would promoted our knowledge to understand the early evolutionary history of Neuroptera.

A developmental approach to the evolution of female wing regression in bagworm moths (Lepidoptera, Psychidae)

Shuhei Niitsu
Tokyo Metropolitan University, Japan

Bagworm moths (Lepidoptera: Psychidae) include approximately 1000 species in the world, all of which complete the larval development within a self-enclosing bag. They show one of the most extreme cases of sexual dimorphism in wing development; females of some species lost their wings completely in relation to their case-dwelling life style, but females of the other species did not. The loss of wings is achieved by: 1) loss of the potential of cell proliferation during wing disc development (subfamily Oiketicinae); 2) wing bud regression caused by apoptosis in the larval and the pupal stages (subfamilies Taleporinae, Psychinae, and Epichnopteriginae). In this study, to examine the evolutionary pattern of such a female wing-regression, we reconstructed a molecular phylogeny of over 20 species of Asian Psychidae based on the sequences of mitochondrial COI and nuclear 28S rDNA. The results suggested that the groups of wingless females appeared from the group of winged females and that the wing loss of the female adult is achieved through different developmental processes that occurred multiply.

Formation of abdominal appendage-like swellings in the *Carabus insulicola* embryo (Coleoptera, Carabidae): The possible relationship to the aquatic origin of Adepahga

Kazuhiro Niikura[1], Yuuki Oosawa[2], Yasuoki Takami[3], Yukimasa Kobayashi[4]

[1]Tokyo Metropolitan University, Japan, [2]Tokyo Metropolitan University, Japan, [3]Kobe University, Japan, [4]Tokyo Metropolitan University, Japan

The successive changes of developing embryos of Carabus insulicola were described from observations based on light and scanning microscopy. Despite of the absence of larval abdominal legs, two pairs of appendage-like swellings, the medial and lateral ones, appear on both sides of each of the first eight abdominal segments of the middle stage embryo. The distal parts of medial swellings of the first abdominal segment later develop into large cup-shaped pleuropodia. As development proceeds, however, the medial ones of the second to eighth abdominal segments become flattened. In the newly hatched larvae, the flattened parts almost correspond to the abdominal hypopleura. The lateral ones also soon become flattened and disappear. Regarding the pleuropodia as the structures being homologous with thoracic legs, the medial swellings of the second to eighth abdominal segments are also homologous with the proximal parts of the thoracic legs, probably coxal parts. The lateral swellings originate in more proximal parts, or subcoxal parts, of the medial swellings. In the newly hatched larvae, the subcoxal parts become the abdominal epipleura; thus, the lateral swellings can be regarded as temporal subcoxal projections. The nature of the lateral swellings is obscure. However, considering the subcoxal origin of the larval tracheal gills in the Gyrinidae embryos suggested by our studies, we can speculate that the lateral swellings are the vestiges of subcoxal tracheal gills, and the ancestral larvae of the Carabidae might have had tracheal gills. This interpretation may provide information favorable to the assumption that the ancestral adephagan was aquatic.

South American "jewel acrolepiids": A molecular phylogeny based on 8 genes reveals they represent a novel lineage of Argyresthiidae (Lepidoptera: Yponomeutoidea)

Jae-Cheon Sohn[1], Charles Mitter[2], Jerome Regier[3]

[1]University of Maryland, U.S.A., [2]University of Maryland, College Park, Maryland, U.S.A., [3]Department of Entomology, University of Maryland, College Park, U.S.A.

Neotropical yponomeutoids are one of the most poorly studied lepidopteran faunas, with many groups still tentatively defined. One example is the genus Dasycarea Zeller, 1877, based on a single female specimen of the type species D. viridisquamata from which the abdomen is missing. Due to the lack of information about the genitalia, different authors have assigned very different taxonomic placement to Dasycarea: Gelechiidae by Zeller (1877), Roeslerstammiidae by Heppner (1984) and Acrolepiidae by Becker (1999). Reexamination of the type species of Dasycarea revealed that it is closely related to at least eight species of South American yponomeutoids which were misidentified as acrolepiids. An updated inventory of the Neotropical yponomeutoids has found over thirty new species belonging to Dasycarea. To define their systematic position, a molecular phylogenetic analysis was performed based on eight nuclear genes, totaling 8,096bp. The resulting tree showed, in contrast to all previous proposals, that Dasycarea is the sister group to Argyresthia, currently placed in its own family, Argyresthiidae. This association is tested by morphology and receives further support.

Braconidae and Ichneumonidae (Hymenoptera) associated with corn pests *Spodoptera frugiperda* (Lep., Noctuidae) and *Dichomeris famulata* (Lep., Gelechiidae) with descriptions of new species.

Angelica Penteado Dias[1], Ivy Frizo Melo[2], Rafael Braga Silva[3], Ivan Cruz[4]

[1]Universidade Federal De Sao Carlos, Brazil, [2]Universidade Federal De Sao Carlos, Brazil, [3]Universidade Federal De Sao Carlos, Brazil, [4]Embrapa Milho E Sorgo, Brazil

The role and importance of biodiversity in agro-ecosystems is widely recognized and it can be used to improve pest management, providing a means of determining the abundance and dynamics of individual species. A major problem in areas of agriculture is the lack of basic research on distribution, abundance and taxonomy of insect pests and their enemies. Spodoptera frugiperda and Dichomeris famulata are important pests on corn crops, widely distributed, presenting, in Brazil a complex of parasitoids with occurrence and distribution poorly studied. The aim of the present work is to update the bionomic and taxonomic knowledge of the S. frugiperda and D. famulata parasitoids from Brazil. Samples of larvae were held during 2010-2011 at the Minas Gerais State, Brazil along the cropping season. The larvae were placed individually in glass tubes, fed with artificial diet, until the emergence of parasitoids identified by two of the authors (AMPD and IFM). From S. frugiperda emerged: Campoletis flavicincta, Ophion flavidus, Eiphosoma laphygmae, Colpotrochia sp. nov. (Ichneumonidae) and Chelonus (Chelonus) insularis, Dolichozele koebelei, Exasticolus sp nov. (Braconidae). The species of Dolichozele and Colpotrochia are recorded for the first time parasitizing S. frugiperda. From D. famulata emerged the Braconidae : Cotesia sp., Glyptapanteles sp., Phanerotoma sp.(fuscovaria group) and Chelonus (Microchelonus) sp. nov. (first occurrence on Dichomeris famulata). Those parasitoids are koinobiont endoparasitoid solitary or gregarious and emerged from larvae or pupae of the hosts. The material is deposited in the Brazilian Collection (DCBU) Sao Carlos, SP. The species are illustrated with digital and SEM images.

New contributions to knowledge of pimplinae wasps (Hymenoptera, Ichneumonidae) from Brazil

Angelica Penteado Dias[1], Ana Paula Silva Loffredo[2]

[1]*Universidade Federal De Sao Carlos, Brazil,* [2]*Universidade Federal De Sao Carlos, Brazil*

This study aimed to contribute to the knowledge of Neotropical fauna of Pimplinae through the characterization and quantification of their genera and species in Southeast of Brazil. Using mainly Malaise traps in 11 localities in the State of Sao Paulo, from 2006 to 2008, we collected 716 specimens of Pimplinae, distributed in 58 taxa , including 15 genera and 33 species (25 possible new species) and new records (14) for the Brazilian fauna. In the tribe Ephialtini were identified specimens of the groups of genera Ephialtes (Scambus, Calliephialtes), Camptotypus (Clydonium, Zonopimpla), Tromatobia (Tromatobia, Clistopyga and Zaglyptus) and Polysphincta (Polysphincta, Acrotaphus, Hymenoepimecis, Eruga and Zatypota) . In the tribe Pimplini, we obtained specimens of the groups of genera Theronia (Neotheronia) and Pimpla (Pimpla). Neotheronia and Hymenoepimecis were the genera with the largest number of species identified, 16 and 9 respectively. Pimpla, Neotheronia and Acrotaphus were the most frequently sampled making up more than 80% of all material, while Calliephialtes, Scambus and Eruga made only 0.56%. We obtained 140 specimens of Pimpla croceiventris, about 19.55% of total and Neotheronia lineata accounted for 17.46% of total of the individuals collected. Regarding the analysis of seasonality, considering the dry season period from April to September and the rainy season from October to March, we have found that the frequencies of occurrence of the species were higher in samples collected during the rainy season. The material is deposited in Brazilian Collection (DCBU) Sao Carlos, SP. Maps of distribution and characterization of the species are presented.

Myrtlemiris, a new genus and new species of Australian plant bugs (Insecta: Heteroptera: Miridae): Systematics, phylogeny and host associations

Marina Cheng[1], Anouk Mututantri[2], Gerasimos Cassis[3]

[1]University of New South Wales, Australia, [2]University of New South Wales, Australia, [3]University of New South Wales, Australia

A new Australian genus of Orthotylinae, Myrtlemiris Cheng, Mututantri & Cassis gen.n., is described, with nine included species described as new to science (M. agnew sp.n., M. astartephila sp.n., M. meanarra sp.n., M. newmanensis sp.n., M. rubrocuneatus sp.n., M. russulatus sp.n., M. silveirae sp.n., M. tesselatus sp.n., M. yalgoo sp.n.). A phylogenetic analysis based on 39 morphological characters is presented for all Myrtlemiris species and 6 outgroup taxa. This analysis establishes Myrtlemiris as monophyletic, defined by a broad apophysis on the left paramere. A key to species is provided and diagnostic characters are illustrated. Myrtlemiris is endemic to southwest Western Australia. Host plants for Myrtlemiris species are near restricted to the myrtaceous tribe Chamelaucieae.

Morphological antennal sensilla in some importance forensic flies In Saudi Arabia

Souad Mohammed Alsaqabi

Faculty Of Science, Dammam University ,Dammam, Saudi Arabia

We investigated the sensilla of the antenna of the some adult flies, Parasarcophaga sp , Musca domestica , Chrysomya megacephala, belonging to Calliphoridae, Sarcophagidae and Muscidae using Scanning Electron Microscopy. Many types of sensilla were observed; no marked differences in morphological structure and distributional pattern of any sensilla among these species with the exception of more numerous sensory pits were found. The suggested function of each antennal sensillum would be based on the comparison with other studies of similar sensilla.

A revision of the genus *Morophagoides* Petersen (Lepidoptera, Tineidae) in Japan

Yohei Osada[1], Toshiya Hirowatari[2], Makoto Sakai[3], Shin-ichi Yoshimatsu[4]

[1]Osaka Prefecture University, Japan, [2]Osaka Prefecture University, Japan, [3]Kyosei-Kagaku, Japan, [4]National Institute for Agro-Environment Science, Japan

The genus Morophagoides Petersen, 1957 consists of 9 species globally, distributed in the Palaearctic, Oriental (Taiwan), Nearctic and Neotropical regions, and some species are well known as pests of the Shiitake mushroom Lentinus edodes (Robinson, 1986). Larvae of this genus injure the bed log and fruit body of the mushroom, and produce a remarkable degree of damage. In order to develop applied methods of controlling the pests using a pheromone or natural enemy, it is necessary to identify species correctly. In Japan, Morophagoides moriutii Robinson, 1986 is known as an important Shiitake mushroom pest (Moriuti, 1976. Inoue, 1988). The larvae feed on the mushroom, and its bed log (Moriutii, 1976). However, the taxonomy of the genus is complicated and controversial. In this study, we found that the genus consists of 9 species, including M. moriutii, M. ussuriensis, and an additional 7 new or unrecorded species in Japan. The 9 species are grouped into 5 species groups based on the male and female genitalia. Emergence time and distribution of the species are compared from the label data of the specimens.

Comparative study of hind-wing venation of Cerambycinae (Coleoptera: Cerambycidae) from China

Li Chen[1], Lichao Tian[2], Zhu LI[3]

[1]Southwest University, China, [2]Southwest University, China, [3]Southwest University, China

A comparative study on hind-wing venation was performed based on 115 species, 53 genera, 18 tribes of the subfamily Cerambycinae. This study finds not only significant differences in venation features of the Cerambycinae at tribe-level and genus-level, but also the evolutionary trends of Cerambycidae. The chosen venation characters could be used in identification of Cerambycinae. The key of Cerambycinae based on characters of hind-wing venation was presented. Cerambycinae could be divided into three types by variation of MP3+4 and CuA1+2 (① Trace of CuA1+2 is clear, fuses with MP4. These two fusing branches reach the posterior margin. ② no trace of CuA1+2, MP3+4 forks into MP3 and MP4. MP4 reaches the posterior margin. ③ no trace of CuA1+2, no forks of MP3+4. Only MP3+4 reach the posterior margin), which showed the most important information of hind-wing in Cerambycinae, and the transition types in wing morphology appeared to reflect evolutionary trends. But venation could be only used for identification of a few species within transition types. We consider the venation nomenclature proposed by Kukalova-Peck and Lawrence (2004) for r4, CuAF, and relation of AA3+4 and cubitus shouldn't used in Cerambycinae. However, the part of cross-vein by Salaas (1936) and Suzuki (1969) is a nice way to solve these questions. So, we consider the best method to make these venation clear is combine the main veins of Kukalova-Peck and Lawrence (2004) and the cross-vein of Salaas (1936) and Suzuki (1969)

Occurrence of an undescribed *Metapocyrtus* species attacking *Hedera helix* in Japan (Coleoptera: Curculionidae: Entiminae)

Hiraku Yoshitake

National Institute for Agro-Environmental Sciences, Japan

Globalization facilitates the spread of pests and alien species throughout the world. In 2010, an undetermined weevil (Coleoptera: Curculionidae) caused serious damage to the cultivated ivy, Hedera helix (Araliaceae), in a farm of ornamental plants in Kuwana County, Mie Prefecture, Central Honshu, Japan. Adult weevils attacked leaves and stems of H. helix, whereas its larvae attacked the roots in the soil. Judging from its morphological features, this pest was considered as a species of the subgenus Trachycyrtus, genus Metapocyrtus (Entiminae: Pachyrhynchini), which comprise about 220 species from Southeast Asia, but it was unable to be identified at species level based only on literature data. In order to identify this pest weevil, I examined major reference collections of Metapocyrtus including many type specimens at the Museum fur Tierkunde, Dresden and the Natural History Museum, London. After careful examination, I concluded that the species in question is different morphologically from all known species and thus new to science. This species, which occurred suddenly and locally in an artificial environment, is considered not to be native to Japan but an invasive species from a Southeast Asian country, most probably from the Philippines that contains the great majority of Metapocyrtus species. However, the invasion route of this species to Japan is still unclear.

Bagworms (Lepidoptera: Psychidae) of the European part of Russia

Julia Lovtsova
All-Russian Center for Plant Quarantine, Russia

Bagworms (Psychidae) is a moderate family of Lepidoptera, which numbers more than 1300 species in the world. The bagworms fauna of many countries of the world is studied quite well, while the bagworms fauna of the European part of Russia was not researched. In this work bagworms of the European part of Russia were investigated. My research is based on own materials, museum collections and literature records. In the course of our investigation we establish that four species Diplodoma taurica, Praesolenobia clathrella, Dahlica wockei, Postsolenobia banatica must be excluded from the checklist of bagworms of the European part of Russia, because their inclusion was a result of a misidentification or incorrect reference. While, two species were recorded for the first time. New generalized checklist of bagworms of the European part of Russia containing 65 species from 32 genera was made . The most numerous subfamilies are Narycinae and Oiketicinae, each of them includes 18 species. The least numerous subfamily are Typhoniinae that includes 2 species. Also subfamilies Taleporiinae (5 species), Psychinae (9 species), Epichnopteriginae (13 species) are represented. Also were found some new records for different regions of the European part of Russia, for example Psychidea alba was found for the first time in the Caucasus, Apterona helicoidella and Rebelia nocturnella was found for the first time in the center of the European part of Russia. Also in the course of my study a special key for identifying males and females was created.

"What is *Tipula (Nippotipula) coquilletti*?": Determined by the holotype examination (Diptera: Tipulidae).

Takashi Torii
Keio University, Japan

Tipula (Nippotipula) is the crane fly subgenus containing mainly large to extra large species, which are distributed in the eastern Palaearctic, Oriental, and eastern Nearctic Regions. Only one species, i.e., T. (N.) coquilletti was recorded from Japan. No information was given on male terminalia in the original description of T. (N.) coquilletti, and no one examined the holotype except the original author. In the present study, a species named T. (N.) sp. 1 was recorded from several localities of Honshu, Japan. The species was closely related to T. (N.) coquilletti in the sensu of several authors (of which no one examined the holotype), but distinguished from the latter only by the details of structures of male terminalia. However, because of the lack of information on male terminalia for T. (N.) coquilletti, it was impossible to determine which is the true T. (N.) coquilletti: tentatively identified T. (N.) coquilletti by the above authors, or T. (N.) sp. 1. The present author had the loan of the holotype of T. (N.) coquilletti from the National Museum of Natural History, USA, and determined that tentatively identified T. (N.) coquilletti is the true T. (N.) coquilletti. The detailed redescription of the species is given in the present study, especially on male terminalia. In addition to this, T. (N.) sp. 1, which is new to Japan or to science, is described as compared with resembling species, T. (N.) sinica, which is recorded from Sichuan and Zhejiang, China.

Keywords:*Tipula (Nippotipula) coquilletti, holotype examination, male terminalia, Tipula (Nippotipula) sp. 1, new to Japan or to science*

Divergence time estimation of fern-feeding sawflies

Yuichi Isaka[1], Toshiyuki Sato[2]

[1]Shinshu University, Japan, [2]Shinshu University, Japan

Most of vascular plants are used to some extent as a food source by phytophagous insects. However, these groups are not used equally, and the Filicales is rarely attacked by members of Insecta. The ratio of fern-feeding insects to fern species in number is lower than that of phytophagous insects to angiosperm species. The extraordinary diversification of angiosperms throughout the Cretaceous and Tertiary, culminating in an estimated 250,000-300,000 living species, is considered. The extraordinary diversification of living insects has been attributed by some workers to the diversity of angiospermous plants. This notion is supported by exhaustive examples of complex ecological coupling between the two groups, especially with regard to insect herbivory and pollination. While, ferns, with more than 10,000 living species, are the second largest group of vascular plants. Most of ferns are considered to be diversified in the Cretaceous. Does fern diversification promote fern-feeder insect diversification? Hymenopteran, especially symphytan, fern-feeders provide a good model system for evolutionary question because the proportion of fern feeders in phytophagous Hymenoptera is higher than in other insect orders. We reconstructed molecular phylogenetic relationships among 25 genera of sawflies, including novel several fern-feeder species of 6 genera, using Bayesian method. We used approximately 2kb of DNA sequence data sets. Most DNA sequence data were already available in GenBank. The fern-feeder was shown into two lineages and the range of divergence time of symphytan fern-feeder was 93-76 Mya calculated by the molecular clock analysis.

Solitary and social halictine bees collected by the Kyushu University expeditions to Central Asia

Ryuki Murao[1], Osamu Tadauchi[2]

[1]Kyushu University, Japan, [2]Kyushu University, Japan

We conducted five surveys to accumulate faunal information on wild bees to assist planting campaigns in Central Asia (Kazakhstan, Kyrgyzstan) and neighboring area (northwestern China) from 2000 to 2004 under the project title "Field Studies of Wild Bee Fauna and Pollination Biology for Combating Desertification and Planting Campaign in Asian Arid Areas" (Tadauchi, 2005). A total of 21,494 bee specimens were collected from Central Asia by this project. The taxonomic result based on this project have been published in following taxa: Colletes (Kuhlmann, 2009), Andrena (Tadauchi et al., 2005; Tadauchi, 2006, 2008; Shebl & Tadauchi, 2009, 2011), Nomada (Mitai & Tadauchi, 2008), and Bombus (Williams, 2011). However, the bee family Halictidae which mostly occupied in the collection (collected 16,613 specimens) is not well studied yet. Recently, one of author's Murao visited to some of European and Russian Museums to study and identify the halictine bees specimens (excluding cleptoparasitic genus Sphecodes) collected by this project. In our presentation, we report a taxonomic result about solitary and social halictine bees collected by the Kyushu University expeditions to Central Asia.

Discrimination methods of a migratory pest, *Spodoptera exempta* occurred in Japan for the first time in 2010 from other similar Japanese pests of the genus *Spodoptera* Guenee (Lepidoptera: Noctuidae)

Daisuke Watabiki[1], Shin-ichi Yoshimatsu[2], Hiraku Yoshitake[3], Yuki Baba[4], Takumi Uesato[5], Masayuki Shimatani[6], Hiroshi Ibusuki[7], Tatsuya Yuda[8]

[1]Tokyo University of Agriculture, Japan, [2]National Institute for Agro-Environmental Sciences, Japan, [3]National Institute for Agro-Environmental Sciences, Japan, [4]National Institute for Agro-Environmental Sciences, Japan, [5]Okinawa Prefectural Plant Protection Center, Japan, [6]Okinawa Prefectural Plant Protection Center, Japan, [7]Kagoshima Prefectural Institute for Agricultural Development, Japan, [8]Kagoshima Prefectural Institute for Agricultural Development, Japan

The genus Spodoptera Guenee mainly distributed from tropical to subtropical regions throughout the world includes many pests of food crops, vegetables, forage crops and grasses. S. exempta has been known from Africa, South East Asia, parts of Australia to some Pacific islands as a pest of crops or pasture, however, no damage by this pest had been reported from Japan before 2010. From Japan, only five adult specimens had been collected before 2010, and probably they flew from tropical region of Asia to Japan because S. exempta is a well known migratory pest in Africa. Severe damage of forage crops and grasses by this species was recognized for the first time from Japan at Nansei Isls. in 2010. Therefore, survey using synthetic sex pheromone for S. exempta was conducted by the Okinawa Prefectural Plant Protection Center and the Kagoshima Prefectural Institute for Agricultural Development. As a result, several species of the genus Spodoptera were collected involving S. exempta by the pheromone trap for S. exempta. For convenience, we made a key to distinguish eight Japanese species of Spodoptera mainly using male genitalia. Furthermore, we could distinguish six Japanese pests of Spodoptera each other using the method of the standard DNA barcoding.

Genetic structure of *Aeolesthes oenochrous* (Coleoptera: Cerambycidae) in Taiwan

Chien-Hsien Chiu[1], Wen-Bin Yeh[2], Man-Miao Yang[3]

[1]National Chung Hsing University, Taiwan, [2]National Chung Hsing University, Taiwan, [3]National Chung Hsing University, Taiwan

Wushe blood-spotted longhorn beetle, Aeolesthes oenochrous (Fairmaire), feeding on domestic cherry tree (Prumus campamulata), is one of the endangered species in Taiwan. In the past decade, the beetle's habitat and population size have increased due to the plantation of cherry trees for tourism. Therefore, in spite of lacking information on the genetic structure and diversity of this species, a consideration of removing it from the conservation list has been proposed. The study herein presents analyses based on mitochondrial COI and nuclear ITS2 genes to investigate the population structure and ongoing gene flow of this beetle. Seven populations with 83 individuals were collected, and 19 haplotypes in COI showed 0.885 in haplotype diversity and 0.004 in nucleotide diversity. AMOVA showed significant COI divergence between populations (average Fst=0.4). In ITS2 sequences, a microsatellite of (CTA)n repeat was found ranging from 5 to 9. Phylogeny and network analysis showed that A. oenochrous populations can be separated into western and widespread clades, indicating two events of colonization or single colonization by the following differentiation has occurred. Moreover, the highest genetic diversity found in both COI and ITS2 sequences indicated that Taoyuan might be one of the possible ancestral populations. According to the population demography, individuals of two lineages occurring in the same localities might due to population expansion. However, a gene flow between populations might be also caused by human activities since dot plot distributions of genetic pairwised distances to their relevant geographical distances showed no positive relationship either in western or widespread clades.

The phylogeny and host specificity of gall midges (Diptera: Cecidomyiidae) inducing similar spindle-shaped leaf galls on ten *Quercus* L. (Fagaceae) species in Taiwan

Hsin-Yen Tsai[1], Man-miao Yang[2]

[1]*National Chung Hsin University, Taiwan,* [2]*National Chung Hsin University, Taiwan*

The interaction between gall-inducing insects and their host plants is a complex part of the evolutionary scenario. In Taiwan, a group of allied gall midges induce similar spindle-shaped galls on leaves of 10 species of subgenus Cyclobalanopsis of genus Quercus (Fagaceae). Our preliminary observations found that a gall midge species may induce similar galls on different host plants; alternatively, different gall midge species are also able to induce similar galls. Thus, it would be desirable to make further investigations and to construct a phylogeny to help clarify the relationships among host plants, gall midges and gall morphology. In this study, molecular sequences of both mitochondrial gene COI and nuclear gene ITS2 from midge larva were used to build molecular phylogenetic trees. Morphological characters of galls were analyzed by ANOSIM similarity analysis for grouping and compared with molecular phylogeny. The result shows that gall midges on C. championii, C. gilva, C. hypophaea, C. morii and C. pachyloma are monophyletic groups and suggests each representing a distinct species. However, gall midges from C. globosa, C. longinux, C. stenophylloides are paraphyletic groups and mixed with samples from C. glauca which suggests these taxa may be recently diverged. The result of the similarity analysis of gall morphological characters was, for most part, consistent with the molecular phylogeny. Although the identification of gall midge species is not fully clarified, the results suggest that midges inducing spindle-shaped galls on Cyclobalanopsis reveal a trend of host specificity, and closely related clades induce similar galls.

Studies on geometridae larvae (Lepidopera) and its parasitoids in southeastern Brazil

Manoel Martins Dias[1], Carolina Silva Souza[2], Mariana Geraldo[3], Angelica Penteado Dias[4]

[1]Universidade Federal De Sao Carlos, Brazil, [2]Universidade Federal De Sao Carlos, Brazil, [3]Universidade Federal De Sao Carlos, Brazil, [4]Universidade Federal De Sao Carlos, Brazil

Larvae of Geometridae (Lepidoptera) were obtained in two areas with native vegetation recovery in Southeastern Brazil, Sao Paulo State. The samples were collected by entomological umbrella, for a minimum of one year. Larvae were kept in the laboratory on their host plants until the emergence of moths or parasitoids. Among the common Geometridae were some species of Macaria, Oxydia, Glena, Hymenomima, Ischnopteris (Ennominae) and Eois (Larentiinae). The Ennominae, in number of species, represents about half of the Geometridae and the results obtained here show the almost complete predominance of species of this subfamily; the Larentiinae and Sterrhinae (Semaeopus and Cyclophora) were not so common. The most common parasitoid species were Euplectrus (Eulophidae), Glyptapanteles, Diolcogaster (Braconidae) and Diradops, Charops (Ichneumonidae). Some of the parasitoids were for the first time found on larvae of Geometridae and included some new species. The studied material was deposited in the collection of the Department of Ecology and Evolutionary Biology, Federal University of Sao Carlos, Sao Carlos, Sao Paulo State, Brazil. Bionomic data on the species are presented. Seasonal variations were observed in the abundance of larvae of Geometridae, as well different relations of specificity of the larvae and their host plants. The greater occurrence of larvae was recorded in March, April and May, corresponding to the final period and immediately after rainfall. The environments of native vegetation recovery were important for the establishment of populations of species of Geometridae and can act as links between fragments of natural vegetation remaining in this region.

Phylogeography of four stag beetle groups (Coleoptera, Lucanidae) in the Ryukyu Archipelago, Japan

Tadatsugu Hosoya[1], Kunio Araya[2]

[1]Kyushu University, Japan, [2]Kyushu University, Japan

Four different groups belonging to the family Lucanidae distributed in the Ryukyu Archipelago and adjacent regions were examined to evaluate each phylogeography, based on the mitochondrial 16S ribosomal RNA gene sequence. The resultant tree of the subgenus Psalidoremus of the genus Prosopocoilus contains two major lineages: one consists of the members collected from mainland Japan and the Osumi Islands, and another from the Ryukyu Archipelago and Taiwan. The latter is further divided into the following two sublineages: the Tokara Islands and the Central Ryukyus, and the Southern Ryukyus and Taiwan. The nucleotide substitutions between them as well as those between two major lineages show a relatively high percentage. The resultant trees both Neolucanus maximus species group and Dorcus amamianus show similar patterns that of the subgenus Psalidoremus living in the Ryukyu Archipelago, with two major lineages, the central and southern Ryukyus, respectively. These common patterns in phylogeography of different three lucanid groups suggest involvement of these lucanid beetles in a series of vicariances in the Ryukyu archipelago and Taiwan regions during the late Pliocene and the early Pleistocene. On the other hand, the resultant tree of Dorcus titanus contains two major lineages: one consists of the Tokara Islands and Amami Island in the central Ryukyus, and another of the remaining regions of the Ryukyu Archipelago, Taiwan and mainland Japan. The nucleotide substitutions between two major lineages show a relatively low percentage. These results indicate that recent migration of Dorcus titanus complicated its current distributional patterns.

Evaluation of the secondary structure of 16S rRNA for molecular phylogeny of Schizophora clade (Diptera: Brachycera)

Ana Carolina Martins Junqueira[1], Daniel Fernando Paulo[2], Ana Maria Lima Azeredo-Espin[3]

[1]State University of Campinas - UNICAMP, Brazil, [2]State University of Campinas - UNICAMP, Brazil, [3]State University of Campinas - UNICAMP, Brazil

The 16S is the largest ribosomal RNA subunit of the mitochondrial DNA and is extensively employed in evolutionary studies of insects. Nevertheless, its structural information has been considered only recently. In this work, the sequence and secondary structure of the 3'-half of the 16S (535 bp) were evaluated as molecular marker for phylogenetic studies of twenty-nine dipteran species of Schizophora clade. The Schizophora comprises one of the greatest insect radiations, but molecular phylogenetics usually concerns its ingroup relationships, highlighting the need for further studies on different hierarchical levels. In this context, secondary structure prediction was performed in silico and based on homology of conserved structural motifs. Phylogenetic signal analyses showed that 3'-half of the16S have appropriate information for phylogeny of hierarchical levels analyzed, increasing when double-stranded sites are considered. For Calyptrate, Bayesian inferences using sequence and structure, supported the monophyly of the superfamily Oestroidea (PP 0.91) and its placement as a sister group of the superfamily Muscoidea. The Rhiniidae have been raised to family status recently and the species used in this work presented two placements in the trees recovered: (Rhiniidae, (Oestridae+Tachiniidae)) and (Sarcophagidae+Rhiniidae). The monophyly of Acalyptratae was not supported and interfamilial relationships recovered the Lauxaniidae as a sister group of (Sepsidae+Drosophilidae) (PP 0.44) and (Sphaeroceridae, (Ropalomeridae, (Micropezidae + Aulacigastridae))) (PP 0.91). Our results indicates that the use of sequence and structure of 16S increase the phylogenetic signal for Schizophora old divergence groups, but presents limitations in some taxonomic levels, probably related to the rapid diversification of schizophoran lineage.

Taxonomic study on *Cryptocercus* Scudder

Dong Wang[1], Yanli Che[2], Zongqing WANG[3]

[1]College of Plant Protection, Southwest University, China, [2]College of Plant Protection, Southwest University, China, [3]College of Plant Protection, Southwest University, China

The present research indicated there were some incorrect identification in previous study, for instance, the species represented by 16S rRNA (DQ007646), COII (DQ007643) and the species represented by 16S rRNA (DQ007647), COII (DQ007644) should not be conspecific, but they were considered as the same species previously, while the species represented by 12S rRNA (AY631411), 16S rRNA (AY631410) and the species represented by 12S rRNA (AJ519679 in EMBL), 16S rRNA (AJ519678 in EMBL) should be conspecific. We used a single gene and combined two or three genes to build phylogenetic trees (methods by Parsimony, Maximum Likelihood and Bayesian). Two new species of the genus Cryptocercus Scudder 1862 were described based on morphological characters and DNA sequence of the three mitochondrial genes (partial sequence): 12S rRNA, 16S rRNA and cytochrome oxidase subunit II (COII). One species was collected from Shennongjia in Hubei Province and mountain Taibai in Shaanxi Province and another from mountain Tianhua in Shaanxi Province. All these places were newly discovered distributions to Cryptocercus.

Analyses of the mating behavior of the Japanese *Auplopus carbonarius* species-complex (Hymenoptera, Pompilidae)

Hiroaki Kurushima[1], Akira Shimizu[2]

[1]*Tokyo Metropolitan University, Japan,* [2]*Tokyo Metropolitan University, Japan*

Members of Auplopus are mud-daubers, which plaster mud in nest construction. Since some Japanese species of this genus exhibit few morphological differences, their classification has been confused. The Auplopus carbonarius species-complex has two morphological types in the male, i.e. the "whitely-spotted mandible type" and "black mandible type". The former has the mandible with a white spot and frons with lateral white bands extending above the level of the antennal socket, and the latter has the black mandible and frons with lateral white bands not extending above the level of the antennal sockets. The purpose of this study is to examine whether behavioral isolation exists between the both type wasps by experiments of copulation. Males and females were paired in petri dishes, and their behavior was recorded with a video camera. In the copulation between the same type wasps, the male moved toward the female with the metasoma raising and the wings vibrating, and then mounted on her. Next, the male inserted its aedeagus into her metasomal tip, when she stopped moving for a while. After beginning to move again, the female drove off the male that exhibited courtship behavior. Between the different type wasps, however, male courtship scarcely occurred and copulation was never successful. Differences in the mounting time and mating behavior were found between the both types. Based on the results, we concluded that behavioral isolation exists between the both types, and it is thus presumed with certainty that these have been differentiated to the species level.

The taxonomic study of the family Stygothrombiidae (Prostigmata:Acari)

Takuya Nagasawa[1], Hiroshi Abe[2]

[1]Nihon University, Japan, [2]Nihon University, Japan

Stygothrombiid mites inhabit interstitices in mountain streams and lakes. However, relatively little has been known about the taxonomy and life-history of these mites. It is also difficult to identify stygothrombiid species because most of the descriptions and illustrations in the past studies do not provide adequate details for a meaningful comparison of the species. Therefore, the purpose of this study is to establish the classification of Stgothrombiidae on the basis of the re-examination of discriminating characters of species and genus. At first, we examined the suitability of generic and specific characters of Stygothrombiidae in past studies. As a result, several generic characters such as the number of setae in crista metopica, existence of a pattern in epidermis, existence of setae in claws, existance of setae in empodium, and the number of setae in glandularia were constant among genera. Therefore, these generic characters should be regarded as characters of familial rank. Although most of the specific characters in the past studies were valid, some additional discriminating characters were newly found. As a result of SEM observation, forms of glandularia on epidermis and odontus on palpi were varied among species. Consequently, these characters can be used for specific identification. We examined the classification of Stygothrombiidae based on the newly established characters. The five genera so far erected Cerberothrombium, Victathrombium, Charonothrombium, Hydorothrombium, Baicalacarus should be synonymized to a single genus Stygothrombium. Consequently, as indicated by Mullen and Vercammen-Grandjean (1980), all species of the stygothrombiid mites should belong to the single genus Stygothrombium.

'Embioptera problem' in relation to an enigmatic taxon Timematodea

Natuo Komoto[1], Kenji Yukuhiro[2], Shuichiro Tomita[3]

[1]National Institute of Agrobiological Sciences, Japan, [2]National Institute of Agrobiological Sciences, Japan, Japan, [3]National Institute of Agrobiological Sciences, Japan

The interordinal relationships within Polyneoptera are highly controversial probably because of ancient and rapid radiations. In order to circumvent the limitations of morphological classification, we sequenced the full length mitochondrial genome of Phasmatodea and Embioptera species and analyzed the molecular phylogeny of polyneopteran insects. There are advantages of mtDNAs for phylogenetic analyses, such as the absence of recombination, introns, and paralogs. PCR-based cloning of mtDNA is also helpful to obtain relatively large data sets. In the course of the analysis, we found novel gene rearrangements in a webspinner, Aposthonia japonica. The phylogenetic analyses showed that Embioptera forms a monophyletic clade with Verophasmatodea, a suborder of typical stick and leaf insects. Timema, which has been thought as an ancestral group of Phasmatodea, was placed as an outgroup of Embioptera + Verophasmatodea. There are discrepancies in intraordinal relationships of Verophasmatodea. For example, the molecular phylogeny of mitogenomes did not support the monophyly of Areolatae and Anareolatae, two major infraorders of Verophasmatodea. Mantophasmatodea and Grylloblattodea were closely related to Phasmatodea and Embioptera, forming a monophyletic clade. Dictyoptera, including the praying mantis, cockroach and termite, was placed as sister to the clade Phasmatodea + Embioptera. Orthoptera was recovered as a monophyletic group distantly related to Phasmatodea.

Taxonomic overview in marine water mites Pontarachnidae

Akira Moto[1], Hiroshi Abe[2]

[1]Nihon University, Japan, [2]Nihon University, Japan

Pontarachnidae is the only family of the superfamily Hygrobatoidea in the subclass Acari occurring in the marine environment. This family contains two genera Pontarachna and Litarachna. Although the water mites of the family are widely distributed around the world, the taxonomic overview of the family has not been given since Viets, K. (1957). And in the former descriptions of the species in the family, the quantitative charcters has been used as major taxonomic characters. In this study, taxonomic characters of species were reconsidered by reviewing specific descriptions in the past studies as well as examining real specimens collected from the Pacific coast in Japan. As a result, it is concluded that most of the quantitative characters so far used in the specific descriptions were not suitable for discriminating taxonomic characters of species. On the other hands, configrations of glanduralia and platelets on the ventral side of body are considered as useful taxonomic characters. The critical review of the past study strongly suggests that Litarachna divergens is junior synonym of Litarachna communis and Litarachna curtipalpis is junior synonym of Litarachna sabangensis because these species were not divided by taxonomic characters newly established in this study.

Since 2009 our teams have carried out DNA barcoding of mealybugs (Hemiptera: Pseudococcidae) and their parasitoids (mainly Hymenoptera: Encyrtidae). Mealybug populations and associated parasitoids have been surveyed on crops and ornamental plants from several regions of the world. Individual samples collected have been characterized by DNA sequencing at 2-5 DNA markers (using non-destructive DNA extraction methods) and then by morphological examination. Based on the characterisation of >3,000 samples, around 50 Pseudococcidae species and 30 parasitoid species have been barcoded and identified. These results make it possible to improve our knowledge of the systematics of these taxonomic groups and to develop diagnostic tools for pest management and biological control. However, many samples characterized by DNA sequencing are still in need of taxonomic identification. In addition, molecular data suggest that numerous taxonomic revisions and investigations on complexes of cryptic taxa are currently required.

A comparative survey of proboscis morphology in tiger moths (Lepidoptera: Erebidae: Arctiinae)

Katherine Habanek[1], Stacey Coy[2], Susan Weller[3], Jennifer Zaspel[4]

[1]University of Wisconsin Oshkosh, U.S.A., [2]University of Wisconsin Oshkosh, U.S.A., [3]University of Minnesota, U.S.A., [4]University of Wisconsin Oshkosh, U.S.A.

Tiger moths are known for their vibrant coloration as well as their unusual feeding behaviors. In particular, some tiger moths sequester toxic compounds such as pyrrolizidine alkaloids, from their host plants for chemical protection as opposed to nutrition. This feeding behavior has been linked to mating behaviors and defense. While tiger moth behavior has been extensively studied, their morphology and evolution has not. This study documents proboscis chemosensory structures in adult tiger moths using scanning electron microscopy (SEM). SEM images of more than 40 species representing Arctiini were taken. Resulting images were used to describe proboscis morphology for all taxa included in this study. Adult pharmacophagous (PA feeders) species had a significantly higher number of chemosensory structures on the proboscis than species that are pharamcophagous as larvae. Putative olfactory sensilla are reported on the proboscis of Nyctemera coleta. Olfactory sensilla on the moth proboscis may play a role in sensing low-volatile plant secondary compound residues.

Species of *Acizzia* (Hemiptera: Psyllidae) as potential new economic pests of solanaceous crops.

Gary Taylor[1], Deborah Kent[2], Alan Yen[3]

[1]University of Adelaide, Australia, [2]Macquarie University, Australia, [3]Victoria Department of Primary Industries, Australia

Two species of Acizzia, A. alternata Kent & Taylor and A. solanicola Kent & Taylor (Hemiptera: Psyllidae) were recently described from the plant family Solanaceae from eastern Australia. Hosts were recorded as Solanum mauritianum Scop. (wild tobacco tree: host for both species) and S. melongena L. (eggplant: for the latter). As both host species were introduced into Australia, it was postulated that these psyllids may have either been accidental introductions from an unknown source, or of Australian origin that had switched hosts from native Australian solanaceous hosts. In 2011, the discovery of an undescribed species of Acizzia from native Solanum lasiophyllum Dunal ex Poiret (flannel bush) from Western Australia supported the hypothesis that this morphologically distinct 'species-group' within the Acizzia originated on Solanaceae within Australia. In early 2012, A. solanicola was recorded for the first time in New Zealand. In Australia, it is now considered a potentially serious pest species of eggplant. Nymphal feeding causes malformation of leaves, wilting, premature senescence and crop loss, although it is yet to be determined whether these symptoms are as a result of feeding alone, or of an undiagnosed transmissable pathogen. Its ability to transmit Candidatus Liberibacter solanacearum, (recorded in New Zealand, but not Australia) in other solanaceous crops (cape gooseberry, capsicum, chilli, tamarillo, potato and tomato) has yet to be assessed. The environmental implications of its potential role in the transmission of Candidatus, or other plant pathogens, in native Australian and New Zealand Solanaceae remains unknown.

Genetic variation and phylogeographic inference of alpine ground beetle (Coleoptera, Carabidae, Nebriini) in Taiwan

Yi-Min Weng[1], Wen-Bin Yeh[2], Man-Miao Yang[3]

[1]National Chung Hsing University, Taiwan, [2]National Chung Hsing University, Taiwan, [3]National Chung Hsing University, Taiwan

Taiwan is located off southeastern coast of China, between Ryukyu and Philippine archipelagoes. During the past two million years, Orogenesis events had produced over 200 peaks higher than 3000 meters in four mountain ranges separated by lower hills and canyons which become an important dispersal barrier for alpine insects. However, glaciations during Pleistocene may make populations moving down and migrating across lower elevation. We tested two glacial refugia hypotheses for alpine carabids in this study; one is nunatak refugia hypothesis which means alpine insects stay in situ in high elevation area and the other is migration hypothesis which has alternative refugia in southern or low elevated area. Phylogenetic structure among carabids in Nebriini based on two mitochondrial (COI and 16S) and two nuclear (wingless and 28S) sequences showed that Nebria niitakana, N. formosana and Leistus smetanai have great divergences in populations between mountain ranges. It means that these species stayed in situ in high mountains without migrations during the recent glaciation and supports nunatak hypothesis. However, L. nokoensis and N. uenoiana showed no population differentiation, and the fixation index and gene diversity data suggested the glacial refugia of these two species should be in the middle of Central Mountain Range or further south. The incongruent support of differentiation hypotheses among these species may be caused by different microhabitat requirements and migration ability, especially on N. uenoiana which evolved functional hind wings and may cover wilder habitats.

Morphological description of *Ptychocroca galenia* Brown & Razowski (Lepidoptera; Tortricidae) immature stages in laboratory conditions.

Lourdes Peralta[1], Margarita Correa[2]

[1]Servicio Agricola y Ganadero, Chile, [2]Facultad de Agronomia e Ingenieria Forestal, Pontificia Universidad Catolica de Chile, Chile

Ptychocroca galenia Brown & Razowski (Lepidoptera: Tortricidae) is an endemic pest from Chile. It belongs to the recently described genus Ptychocroca, and the only information available for this species is the morphological description of the adult stage. The objective of this work was to study the morphology of immature stages. We describe the complete development of the progeny of an adult couple, reared in laboratory and fed with different substrates available in the area on which the adults were collected. Oviposition was in flatted, clumped eggs, with a completely reticulated chorion, in groups from two to five. From the first stage the larva presents a light brown head with a dark stripe slightly hinted to semi-complete in the gena area, brown protorax shield with a clearer divisor line at the center and a dark anal comb. A rough cuticle, with microspines and dark pinnacles in contrast with the rest of the body can be observed at the second larval stage. By the third larval stage the color of the larva is creamy, slightly pink. The pupa is described in details, being similar to others of the same family. Differences between this species pupa and others very similar are given. No inference about substrate preferences was possible. This study is the first made on P. galenia; it provides better morphological criteria for recognition of immature stages.

Revision of Western Japanese *Galloisiana* (Grylloblattodea): From a standpoint of female body characters

Toshiki Uchifune

Yokosuka City Museum, Japan

In Japan, six species of the genus Galloisiana Gurney, 1948 have been reported. The Westernmost Japanese species, G. notabilis Silvestri, 1927, was described based on only one larva specimen and its description is lacking in information. Another Western Japanese species, G. chujoi Gurney, 1961, was reported based on an adult, but the described characters are insufficient for interspecific comparison. To revise Japanese Galloisiana species, detailed description of G. notabilis and G. chujoi based on adult specimens is necessary. Some specimens containing one adult female were collected from each type locality (Nagasaki Prefecture for G. notabilis and Kagawa Prefecture for G. chujoi) and studied in detail. It was revealed i) that the characteristics of the penultimate instar larva collected at the type locality of G. notabilis correspond to the description by Silvestri (1927), ii) that the females from the two type localities are similar in some important characters such as eyeless, small number of setae on the cervical sclerites, and the shapes of femur and tibia, suggesting that these two species should be synonymous with each other, and iii) that the above mentioned characters are clearly different in other four species of Japanese Galloisiana. To further the revision of the Galloisiana group, it is important to obtain male specimens of G. Notabilis and G. Chujoi, to identify new specimens recently collected from other habitats in Western Japan, and to compare Western Japanese species with Korean species.

Taxonomic study of the genus *Altica* (Coleoptera: Chrysomelidae: Alticinae) from Japan, with emphasis on the morphology of the male and female genitalia, and mouth parts

Haruki Suenaga

Department of Ecology and Systematics, Japan

The flea-beetle genus Altica is widely distributed in all major biogeographic regions except the Antarctica. The genus Altica contains about 250 valid species, of which 13 species and one subspecies are known from Japan (Ohno, 1960; Kimoto and Takizawa, 1994; Lobl and Smetana, 2010). This genus includes agricultural pests such as A. fragariae, which feeds on strawberry leaves. Therefore, accurate identification of Altica species is essential for effective control of agricultural pest species. Nevertheless, it is difficult to identify Altica species based on the external morphology, because most of the species have similar external morphology and body color. It is suggested that Altica species can be identified mainly based on mandibles, the male genitalia, styli, speculum and spermatheca (e.g. Konstantinov, 1987; Kangas and Rutanen, 1993; LeSage, 1995). Although the male genitalia have been studied for Japanese species of the genus Altica, mandibles and female genitalia have not been well described. Thus, female specimens of Altica were sometimes misidentified, and there are some taxonomic confusions. In the present study, I taxonomically revised the genus Altica in Japan, with special emphasis on the morphology of mandibles, male genitalia, styli, spiclum, and spermatheca. As a result, a total of 15 species and one subspecies are recognized from Japan. These species can be reliably distinguished not only by the male genitalia as suggested by previous studies, but also by mandibles and female genitalia.

The morphology of the apical portion of abdomen in the Genus *Malthodes* (Coleoptera: Cantharidae): Search for taxonomic characters in male and female

Naoki Takahashi
Kyushu University, Japan

The genus Malthodes is characterized by having the 9th abdominal sternite more or less well developed in the male and this feature is useful for species identification though the sternite is sometimes similar in general appearance among the species. In marked contrast to the male, females are often very similar to one another and indistinguishable by external morphology. Therefore, identification based upon female characters has seldom been attempted. Twenty-five species of the genus Malthodes have been known from Japan, but many undescribed congeners have been collected from various localities in recent years and female material remained undetermined. In the course of my revisional study of this genus in Japan, the males of 24 species and the females of 15 species including five undescribed species on each sex were examined, and then the developed 10th tergites in the males or the depressed abdominal tergites in the females ["copulatory depression" (Takahashi, 2001)] were found in some congeners. In addition, some differences between the female congeners in the shape of terminalia were recognized. These characters are regarded as the possible key characters for identifying species in the genus, particularly in the female.

[1]The University of Tokyo, Japan, [2]Royal Government of Bhutan, Bhutan, [3]Royal Government of Bhutan, Bhutan, [4]The University of Tokyo, Japan, [5]The Research Institute of Evolutionary Biology, Japan, [6]Yokohama City, Japan, [7]The Research Institute of Evolutionary Biology, Japan, [8]Amagasaki City, Japan, [9]Royal Government of Bhutan, Bhutan, [10]Royal Government of Bhutan, Bhutan, [11]Royal Government of Bhutan, Bhutan, [12]NHK (Japan Broadcasting Corporation), Japan, [13]NHK (Japan Broadcasting Corporation), Japan, [14]NHK (Japan Broadcasting Corporation), Japan

The papilionid butterfly, Bhutanitis ludlowi Gabriel, 1942, was discovered from Bhutan in 1933 and 1934. Since its discovery many researchers and collectors have attempted to rediscover this mysterious swallowtail but without success. In August 2009 and 2011, we rediscovered this species after a lapse of 76 years since it was first collected in Trashiyangtse Valley of Trashi Yangtse, eastern Bhutan. At the same time, the immature stages of this butterfly were recorded for the first time. In this presentation, we describe and illustrate morphological and biological features of B. ludlowi based on observations of the adult, egg and larval stages. The most noteworthy feature is its oviposition strategy. This species lays its eggs in a mound composed of about 100-180 eggs. As far as we are aware, this type of egg-laying behavior has not been recorded in the Papilionidae. We show the affinities to and differences from the other three Bhutanitis species, in particular the closely related B. lidderdalii Atkinson. We also briefly discuss its habitat, conservation needs and biogeography.

World Larainae (Coleoptera: Elmidae) - Taxonomy, phylogeny and distribution

Fedor Ciampor Jr[1], Kristina Lassova[2], Zuzana Ciamporova-Zatovicova[3]

[1]Institute of Zoology Slovak Academy of Sciences, Slovakia, [2]Institute of Zoology Slovak Academy of Sciences, Slovakia, [3]Institute of Zoology Slovak Academy of Sciences, Slovakia

The subfamily Larainae includes 28 genera and around 130 species. The group is distributed worldwide, however the greatest species diversity is in the Afrotropical and Neotropical regions. Larainae represents distinct group of semiaquatic beetles within family Elmidae, distinguishing by many morphological and ecological features. The taxonomy and phylogeny of the group is however still very poorly known. For reconstrucion of the phylogeny and taxonomy of Larainae we used several mitochondrial and nuclear DNA fragments. For the analysis, the samples representing about half of the world genera were available (the largest collection of Larainae samples usable for DNA analysis). We have tested monophyly of the group, relationships with other Elmidae genera and we also assessed the phylogenetic position of several genera with deviated morphological features. Based on the latest information, the updated checklist of genera is provided including notes on the world distribution of the subfamily. Beside population study, the data on intraspecific variability will serve for development of determination technology of animal species using DNA. This contribution/publication is the result of project implementation (ITMS: 26240220049) supported by the R&D OP funded by the ERDF.

The preliminary phylogeny of the Epicopeiidae (Lepidoptera, Geometroidea)

Chia-Hsuan Wei[1], Shen-Horn Yen[2]

[1]National Sun Yat-Sen University, Taiwan, [2]National Sun Yat-Sen University, Taiwan

The Epicopeiidae comprises about only 20 species endemic to the eastern Palaearctic and Oriental regions. Adults of this family are conspicuous with variable wing shapes and involve mimicry with many lepidopteran groups, such as Papilionidae, Riodinidae, Nymphalidae, Geometridae, and Lymantriidae. The family was previously only consist of the type genus Epicopeia. The remaining genera such as Amana, Chatamla, Parabraxas, Psychotrophia, Schistomitra, Deuveia and Burmeia were subsequently transferred to this family from an older concept of Epipleminae (Uraniidae). The family was associated with Drepanidae for a long time until recent studies prove its affinity with Geometridae and Uraniidae. The internal relationships of the Epicopeiidae were only assessed using morphological characters and limited taxa and a hypothetical outgroup. In the present study, we reconstructed the first phylogenetic hypothesis of this peculiar family using nucleotide sequence information from two genes, COI and Ef1a, and Bayesian analyses. The preliminary results show that the family is monophyletic, while some genera may not be monophyletic and it suggests that the mimicry with butterflies may have evolved independently in different lineages and some cryptic species are revealed by the present study.

Asian Species Information Databases KONCHU and AIIC Based on Asian Insects

Osamu Tadauchi
Kyushu University, Japan

Publicly available entomology databases KONCHU and AIIC (Asian Insect Information Center database) were constructed. The former is a general database name which includes various files of bibliographical, image and inventorial databases. The bibliographical database, KONCHUR, is a taxon-based entomology database based on the main Japanese and Pacific entomological journals (24 journals (= files) at present). It includes many East Asian and Pacific as well as Japanese insects. The image database includes useful Japanese insects, bees and encyrtid parasitic wasps with images. The inventorial database, MOKUROKU (Check list of Japanese insects) and DJI (Dictionary of Japanese insect names) cover all the Japanese insect names. The latter, AIIC, is aimed for the accumulation of insect data of type specimens and normal specimens deposited in universities, institutions and museums in Japan. Each record was written according to the format of Darwin Core of the Global Biodiversity Information Facility (GBIF). The records in KONCHU and AIIC are written mainly in English. It is administered by a SIGMA management system. Outlines of the KONCHU and AIIC are presented. A user can access the database files by visiting the following URLs: http://konchudb.agr.agr.kyushu-u.ac.jp/ and http://aiic.jp/.

Status of Phalangopsidae (Orthoptera, Grylloidea) from the atlantic forest of Brazil: Diversity, distribution and founds of recent expeditions

Pedro Guilheme Barrios de Souza Dias[1], Marcio Perez Bolfarini[2]

[1]University of Sao Paulo, Brazil, [2]Sao Paulo State University, Brazil

Phalangopsid crickets are known as long-legged or spider-like crickets due its large development of posterior legs. Besides, the large scape, the shape of head, palpi, tibial spurs and male genitalia comprises the main characters used to define this taxon. Phalangopsidae currently includes 903 species in the world and is a well distributed cricket's family in Neotropics, being the most common on the understories of tropical forests; its species inhabits the leaf litter, trees, trunks, barks and any kind of natural cavities, including caves. In Brazil the phalangopsid's fauna comprises 31 genera and 76 species in three subfamilies (Luzarinae, Phalangopsinae and Paragryllinae). Although phalangopsid species are distributed throughout Brazilian biomes, mainly on tropical forests, its diversity is poorly known: only 8 species are cited from Brazilian Amazonia and 40 from Atlantic Forest. This second one is a tropical forest occurring along the atlantic coast and now considered a biodiversity hotspot due it's great number of endemic species and fragmentation; only 7% of this forest is preserved. The Brazilian studies on taxonomy of crickets are still unsatisfactory in comparison with the extant diversity: only 24 species were described over the last 10 years. Here it will be presented maps of distribution of Phalangopsidae in Brazilian territory, results of recently expeditions through the Atlantic Forest and the presentation of several new species found. It's expected that with efforts on field works and formation of specialists, the number of cricket species will greatly increase, expanding our knowledge on Neotropical cricket's fauna.

Phylogeny of the neotropical social wasp *Synoeca* (Hymenoptera, Vespidae, Polistinae)

Fernando Barbosa Noll[1], Luiz Fernando Fracassi Gelin[2], Raduan Alexandre Soleman[3]
[1]UNESP, Brazil, [2]UNESP, Brazil, [3]UNESP, Brazil

Synoeca is a genus of Neotropical social wasps with five species. Phylogenetic studies based on morphological characters have been controversial because of the polymorphic nature of some phenotypic characters used. In the present work we combine molecular and morphology to perform a phylogenetic analysis of the group. Specimens of the five species and outgroups were collected and preserved in ethanol 100%. Standard molecular techniques were performed to extract, amplify and sequence genetic data from the mitochondrial (cytochrome oxidase I, 12S and 16S) and nuclear (28S, histone 3 and elongation factor 1 alpha) genomes. The sequences were analyzed and the alignment was performed using the software MUSCLE. The gathered data totalizes 5279 characters for eight species. The searches for the best tree were performed using the software TNT where a strategy of combined algorithms was used. Resampling analyses were performed originating Jackknife absolute frequencies and GC values. We found 1 most parsimonious trees with 646 steps, ci 88, ri 72, showing the relationship (Protopolybia (Charterginus (Metapolybia ((Synoeca virginea, Synoeca chalibea), (Synoeca septentrionalis (Synoeca cyanea , Synoeca surinama))))). These results support previous works where polymorphic morphological characters are not taken into account for phylogenetic studies.

Ants diversity on agroecosystems in the Tak Province, Thailand

Chamaiporn Buamas[1], Chalida Unahawuti[2]

[1]Plant Protection Research and Development Office, Entomology and Zoology Group, Thailand, [2]Plant Protection Research and Development Office, Entomology and Zoology Group, Thailand

The present study aims to see diversity of ants between land use types in agroecosystems in the Tak Province of Northern Thailand. A survey was conducted to determine the species of ants in the agroecosystems at the Center of Agricultural and Development. Ants were collected in two locations, tea orchard and avocado orchard. Three sampling methods namely honey bait-traps, cheese bait-traps and pit fall traps were used. A total of 26 species belonging to four subfamilies of ants were collected. The subfamily Myrmicinae had 11 species, Ponerinae 9 species, Formicinae 5 species and Dolichoderinae 1 species. The tea orchard collected 17 species with the dominant genus, Crematogaster, trapped from honey-bait traps and cheese bait-traps. The pit fall traps collected Anoplolepis gracilipes Smith The genuses found in the tea orchard were Aphenogaster, Crematogaster, Polyrhachis and Oecophylla. The avocado orchard collected 16 species with Dolichoderus as the dominant genus from honey bait-traps and cheese bait-traps. Paratrechina longicornis and Pheidole sp.1 were found in the pit fall traps. Three Genuses found in avocado orchard were Amblyopone, Dolichoderus and Paratrechina.

Revision and phylogeny of Chinese *Phaedon latreille* and related genera (Coleoptera: Chrysomelidae: Chrysomelinae)

Sigin Ge[1], Mauro Daccordi[2], Jun-Zhi Cui[3], Xing-Ke Yang[4]

[1]Institute of Zoology, Chinese Academy of Sciences, China, [2]Institute of Zoology, Chinese Academy of Sciences, China, [3]Institute of Zoology, Chinese Academy of Sciences, China, [4]Institute of Zoology, Chinese Academy of Sciences, China

The leaf beetle genus Phaedon Latreille, 1829 from China are revised and illustrated. A key to the Chinese species, a generic redescription, distributional records, the natural history of the genus including the host plants records are provided. The phylogeny based on 50 exoskeletal and genitalic characters from six genera as ingroup (Neophaedon Jakobson, 1901, Phaedon, Prasocuris Latreille, 1802, Sclerophaedon Weise, 1882, Sternoplatys Motschulsky, 1860, Yunnaedon Daccordi & Medvedev, 1999) and one genus (Timarcha Latreille, 1829) as outgroup suggests a clade comprising Neophaedon and Phaedon, another clade comprising Yunnaedon and Sclerophaedon as the monophyly groups. The strict consensus tree of the analysis is not well resolved by both PAUP and Winclada. Nevertheless, considering the results of the initial analysis and the apparent instability of the phylogenetic results based on morphological data alone, we decided to maintain the generic rank of all genera at this stage. A biogeographic analysis for Chinese Phaedon is also discussed. Whereas only Phaedon brassica Baly, 1874, P. cochleariae Fabricius, 1792, P. armoraciae Linnaeus, 1758 are restricted to relatively low altitude, the other species show a major radiation in the Hengduan Mountain Region above 2800 m, which is presently the center of diversity of the genus. Most of these species are flightless and show a preference for scree slopes and rock crevices.

Taxonomic revision of the family Tettigometridae from Korea (Homoptera: Fulgoromorpha)

Mohammad Atikur Rahman[1], Yong Jung Kwon[2], Sang Jae Suh[3]

[1]Kyungpook National University, Republic of Korea, [2]Kyungpook National University, Republic of Korea, [3]Kyungpook National University, Republic of Korea

The planthopper family Tettigometridae, one of the smaller fulgoroid families in Korea, is revised taxonomically. In the revision, three species are confirmed and one species, Tettigometra (Mimarada) bipunctata Matsumura, is unavailable in our current investigation. Among three species, Tettigometra (Tettigometra) burjata Kusnezov, 1929 is new to Korea, and Tettigometra (Macrometrina) sobaeksana sp. nov. is new to science. Previously recorded Tettigometra (Macrometrina) grossa Lindberg in the Korean checklist is treated Tettigometra (Macrometrina) fusca (Melichar, 1902) herein following the description of Emeljanov (1980). All species are described and illustrated, and identification key to subgenera and species from Korea are provided.

A molecular phylogenetic study of the Korean Omaliinae MacLeay (Coleoptera: Staphylinidae)

Tae-Kyu Kim[1], Kee-Jeong Ahn[2]

[1]Department of Biology, Republic of Korea, [2]Department of Biology, Republic of Korea

A phylogenetic analysis of the Korean Omaliinae MacLeay is presented based on molecular characters. The data set comprised partial mitochondrial COI (1501 bp), COII (372 bp), 12S rDNA (351?356 bp), and nearly complete sequences of 18S rDNA (1852?1862 bp) for 20 species. Nineteen omaliine species in 12 genera and four outgroups were included. The sequences were analyzed simultaneously by parsimony, maximum likelihood (ML), and partitioned Bayesian analysis for the combined data. In all analyses, the tribe Eusphalerini Hatch were supported as being monophyletic (clade A) and the genus Geodromicus Redtenbacher formed a clade with the tribe Eusphalerini. Also, Omaliini MacLeay (clade B), and Camioleum choi Shin and Ahn and Olophrum sp.1 showed a sister group relationship (clade C). The tribe Coryphiini Jakobson was monophyletic in two analyses (clade D). The genus Uenohadesina Smetana was a sister group to Trigonodemus koreanus Kim and Ahn in parsimony analysis (clade E), but it formed a clade with Camioleum choi and Olophrum sp.1 (clade F) by the other two analyses.

Generic review of the tribe Athetini (Coleoptera: Staphylinidae: Aleocharinae) in Korea

Seung-Gyu Lee[1], Kee-Jeong Ahn[2]

[1]Department of Biology, Republic of Korea, [2]Department of Biology, Republic of Korea

The Athetini Casey, containing thousands of species in 219 genera, are the largest and the most taxonomically difficult tribe in the Aleocharinae. They are dominant predators in diverse microhabitats and undoubtedly the most successful small beetles. In spite of their taxonomical and ecological diversity, members of Athetini are poorly characterized, but in general, they are distinguished from other aleocharine genera by combination of the following characters: coeloconic sensilla on antenna absent; frontal suture absent; maxilla with four palpomeres; labium with three palpomeres; tarsal formula 4-5-5; athetine bridge of the aedeagus present. In the Palearctic, 1931 species have been recorded in 90 genera. In Korea, Bernhauer was the first entomologist who reported one athetine species in 1923. Later, Pa?nik (2001) presented a taxonomic study including 82 species in 22 genera from North Korea. Currently, a total of 90 species in 23 genera has been recorded in the Korean peninsula. Five genera are discovered for first time from the Korean peninsula (Earota Mulsant & Rey, Enalodroma Thomson, Osakatheta Maruyama et al., Saphocallus Sharp, and Thamiaraea Thomson). As a result, we recognize 28 athetine genera from the Korean fauna representing about 30% of the Palearctic fauna.

Phylogeny of the subtribe Homalotina Heer (Coleoptera: Staphylinidae: Aleocharinae)

Yoon-Ho Kim[1], Kee-Jeong Ahn[2]

[1]Department of Biology, Republic of Korea, [2]Department of Biology, Republic of Korea

A cladistic analysis of the subtribe Homalotina Heer is presented. Seventeen homalotine species in nine genera and eleven outgroups are included. The subtribe is hypothesized to be a monophyletic group consisting of nine genera (Anomognathus Solier, Cephaloxynum Bernhauer, Holisomimus Cameron, Homalota Mannerheim, Homalotina gen. nov., Neomalota Cameron, Paractocharis Cameron, Stenomastax Cameron, Thecturota Casey) based on following synapomorphies: body dorsoventrally strongly flattened, head as wide as pronotum, and antennae inserted anterior to a line drawn between anterior margins of eyes. A history of the classification of the Homalotina is discussed. The data set for phylogenetic analysis comprised 113 characters representing 371 character states derived from adult morphology.

A review of the coastal Staphylinidae (Coleoptera) in Korea

In-Seong Yoo[1], Kee-Jeong Ahn[2]

[1]Department of Biology, Republic of Korea, [2]Department of Biology, Republic of Korea

The family Staphylinidae are one of the most diverse beetle families containing about 55,440 species in 32 subfamilies from the world. In Korea, 557 species in 15 subfamilies have been recorded. They are found nearly all habitats on earth, such as forest, riverside, alpine region, cave, seashore, and so on. Frank and Ahn reported 392 staphylinid species in 92 genera confined to seashore habitats (include intertidal and splash zone, but exclude coastal sand dune) worldwide. In Korea, a total of 36 species in 18 genera has been known from various microhabitats (e.g. under seaweeds/seagrasses, under stones, under debris, empty barnacles/shells etc.) of coastal environs, since Lobl described Briara palpalis (= Prosthecarthron sauteri Raffray) from North Korea in 1974. Species diversity of the Korean coastal rove beetles comprises about 9.2 % of worldwide and they represent four subfamilies (one in Pselaphinae, 23 in Aleocharinae, two in Paederinae, 10 in Staphylininae). Here, we investigated the diversity of Korean coastal species in terms of species numbers among countries, taxa (subfamily level) and microhabitats.

Diversity of diving beetles (Coleoptera: Dytiscidae) in Korea

Dae-Hyun Lee[1], Kee-Jeong Ahn[2]

[1]Department of Biology, Republic of Korea, [2]Department of Biology, Republic of Korea

Diversity of Diving Beetles (Coleoptera: Dytiscidae) in Korea Dae-Hyun Lee and Kee-Jeong Ahn Department of Biology, Chungnam National University, Daejeon, Korea The family Dytiscidae are the most diverse family among water beetle families and live in nearly every aquatic freshwater ecosystem. Members of the family Dytiscidae are characterized by combination of following characters: body shape streamlined; antenna with 11 antennomeres and filiform; metacoxa anteriorly strongly expanded; metaventrite without transverse suture and beak shaped on lateral parts; metacoxal process with large outer lobes; simultaneous hind leg movements. The Dytiscidae contain about 4,100 species in 190 genera (27 tribes, 10 subfamilies) from the world. In Korea, 59 species in 20 genera (13 tribes, 6 subfamilies) have been recorded; 279 species in China, 112 species in Japan, 51 species in Taiwan and 97 species in Far East of Russia. In 1886, Kolbe first discovered four species from Korea. Later, Mori (1932) reported 27 species including one new species. Cho was the first Korean beetle taxonomist who described 24 species in 1969. Since then, about 15 Korean entomologists and a few foreign entomologists have been adding 35 dytiscid beetle species to the Korean fauna.

Korean species of the genus Lordithon Thomson (Coleoptera: Staphylinidae: Tachyporinae)

Young-Gyu Ban[1], Kee-Jeong Ahn[2]

[1]Department of Biology, Republic of Korea, [2]Department of Biology, Republic of Korea

The genus Lordithon Thomson contains 134 species and distributed worldwide. In Korea, two species (L. bicolor Gravenhorst, L. simplex Sharp) have been recorded. Members of the genus Lordithon are characterized by the combination of the following characters: body narrowly fusiform, strongly narrowed from elytral apex to both front of head and anal end; rather convex; surface glossy; elytra usually yellowish-red to reddish-brown with dark brown to black maculations. In this paper, we report five Lordithon species, three of which are identified for the first time in Korea (L. aitai Li & N. Ohbayashi, L. ohbayashii Li & Zhao, L. semirufus Sharp). A key, diagnoses, habitus photographs and line drawings of diagnostic characters are provided.

A taxonomic review of the subfamily Anteoninae (Hymneoptera: Chrysidoidea: Dryinidae) from South Korea, with description of a new Species

Chang-Jun Kim[1], Jong-Wook LEE[2]

[1]Yeungnam University, Republic of Korea, [2]Yeungnam University, Republic of Korea

The subfamily Anteoninae R.C.L. Perkin, one of the largest subfamilies within the family Dryinidae, consists of 502 extant species in five extant genera: Anteon Jurine, 1807; Deinodryinus R.C.L. Perkins, 1907; Lonchodryinus Kieffer, 1905; Metanteon Olmi, 1984; Prioranteon Olmi, 1984 around the world. And, there are 44 species in four genera recorded from the Palaearctic region. Until now, only one genera and four species of Anteoninae, Anteon koreana, Anteon javanum, Anteon jurineanum and Anteon munitum, have been reported in South Korea. Members of the Anteoninae are the ectoparasitoids of Cicadellidae (Hemiptera: Auchenorrhyncha). Most species of the subfamily are important in natural control of agricultural. Types are all deposited in Yeungnam University, South Korea. The new and newly reordered taxa are listed as follows: A new species, Anteon sp. nov. and eleven unrecorded species, Anteon achterberi Olmi, 1989; Anteon ephippiger (Dalman, 1818); Anteon esakii Yasumatsu, 1960; Anteon flavicorne (Dalman, 1818); Anteon insertum Olmi, 1989; Anteon medium Olmi, 1997; Anteon pilosum Xu, Olmi & He, 2010; Anteon reticulatum Kieffer, 1905; Anteon septentrionale Xu, He & Olmi, 2002; Anteon takenoi Olmi, 1995; Lonchodryinus infuscatus Xu, Olmi & He, 2009. Additionally, Anteon medium from China and Anteon esakii from Russia are recorded for the first time. In this study, the sixteen South Korean species of Anteoninae are reviewed, and one new species, Anteon sp. nov. Kim and Lee are described. A key to the South Korean species, the illustrations and photographs of diagnostic characters are provided herein.

The distribution of *Autocrates maqueti* (Coleoptera: Trictenotomidae) in Korea

Jinyoung Park[1], Kyung Ho Kim[2], Seong Joon Park[3], Jong Kyun Park[4], Jong Eun Lee[5], Jin Young Park[6], Myung Jin Kim[7]

[1]Kyungpook National University, Republic of Korea, [2]Yeongyang-gun, Republic of Korea, [3]National Institute of Environmental Research, Republic of Korea, [4]Kyungpook National University, Republic of Korea, [5]Andong National University, Republic of Korea, [6]National Institute of Environmental Research, Republic of Korea, [7]National Institute of Environmental Research, Republic of Korea

The genus Autocrates Thomson, 1860 is currently represented by four species in the world fauna, namely A. aeneus (Westwood, 1846), A. maqueti Drumont, 2006, A. oberthueri Vuillet, 1910 and A. vitalisi Vuillet, 1912. Two of them, A. aeneus (Westwood) and A. vitalisi Vuillet, are widely distributed in the Oriental and South-East Palaearctic regions, while A. oberthueri Vuille, is limited to South China, and A. maqueti has been recently described from central and South China. New species to the fauna of the Korean peninsula; the most North-eastern record for the genus Autocrates. This species has longer been misidentified as aberrant A. aeneus, but after A. maqueti has been described (Drumont, 2006), status of Korean specimen has been completely clarified. Lin et al. (2008) presented review on distribution of Autocrates in China with notes on general distribution of each species. The most northern record for the genus Autocrates recorded before was a record of A. maqueti from Central China. The current record of the Korean A. maqueti is the most eastern and northern known record for this species and for the genus Autocrates in general. General distribuction of this species is still unclear. So far, we introduce of the investigation the state of distribution of A. maqueti in Korea. After more thorough investigation of its ecological data. Also, for this species we will conduct ongoing monitoring. This study was supported by ME & NIER (Survey on Ecosystem and Landscape Conservation Areas)

A preliminary report of the Family Therevidae in Korea (Diptera: Asiloidea).

Dong-Han Kim[1], Ho-Yeon HAN[2]

[1]Yonsei University, Republic of Korea, [2]Yonsei University, Republic of Korea

The family Therevidae is one of the large families of Brachycera flies with 99 recognized genera and about 1,600 described species in the world. They are known to occur in all the zoogeographical regions. They prefer bushy edges of woods, often visibly alight in sunny patches on dry sandy areas, rocks, or trunks of trees. They can fly very fast for a short distance. Some larvae are known as leaf mould and humus eaters. Some species can be found under rotten tree bark and in decaying fruit. The family can be distinguished from the other families of Asiloidea by the following characteristics: 1) antennae with long scape, short pedicel and elongated flagellomere 1, 2) head almost hemispherical and not excavated at vertex, 3) slender to moderately thick body, 4) abdomen with eight well developed pregenital segments, 5) wing venation usually without vein $M_3$and 6) the costa extending around the entire wing. In Korea, there are five previously recorded species. As a result of ongoing investigation of the Korea Therevidae, we have so far recognized 15 species.

Taxonomic review of the genus *Epistrophe* (Diptera: Syrphidae) in Korea

Hak-Seon Lee[1], Seul-Ma-Ro Hwang[2], Ho-Yeon Han[3]

[1]Yonsei University, Republic of Korea, [2]21stC Life Science Foundation, Republic of Korea, [3]Yonsei University, Republic of Korea

The genus Epistrophe is a relatively large genus with 51 recognized species of predominantly Palaearctic distribution (40 species). There are also 7 Oriental, 8 Nearctic and 1 Australian species. They can be distinguished from other syrphid genera by combination of the following characteristics: 1) scutum usually shiny to subshiny black with yellow pruinosity laterally; 2) anterior anepisternum, anepimeron, meron, and metapleuron bare; and 3) katepisternum with dorsal and ventral pile patches narrowly joined posteriorly (subgenus Epistrophe) or broadly separated (subgenus Epistrophella). In Korea, only three species have been previously recorded. In the present study, we have recognized the following seventeen Korean Epistrophe species: 1) eight possible new species: E. n. sp. A to H; 2) six new to Korea: E. aeka Kimura, E. aino (Matsumura), E. annulitarsis (Stackelberg), E. griseofasciata (Matsumura), E. sasayamana (Matsumura), E. shibakawae (Matsumura); and 3) three previously recorded Korean species: E. flava Doczkal and Schmid, E. grossulariae (Meigen), E. nitidicollis (Meigen). We here provide a key and photographs with their key characters indicated.

A preliminary list of the family Tachinidae (Diptera) in Korea

Han-saem Lee[1], Hye-woo Byun[2], Hyun-suk Lee[3], Jong-su Lim[4], Dong-jun Cha[5], Ho-yeon Han[6]

[1]Yonsei University, Republic of Korea, [2]National Institute of Biological Resources, Republic of Korea, [3]Yonsei University, Republic of Korea, [4]Yonsei University, Republic of Korea, [5]Yonsei University, Republic of Korea, [6]Yonsei University, Republic of Korea

The family Tachinidae is the second largest family of Diptera with approximately 10,000 described species and many thousands of undescribed species world wide. Most tachinid flies are noticeably bristled, but their body shape and size vary across the family. In addition to the features shared with other Oestroidea, adult tachinids possess a well-developed subscutellum, a rounded bulge below the thoracic dorsum. As tachinids are internal parasitoids of other arthropods (mostly insects) in their larval stage, they are considered to be aeconomically important group as natural enemies against agricultural and forestal pests. Tachinids employ direct or indirect strategies in attacking their hosts. Despite their economic and ecological importance, relatively little research has been conducted. In Korea, 104 species under 63 genera of Tachinidae have been previously recorded with many suspicious identifications. As an on-going systematic study of Korean Tachinidae, we have so far identified 150 genera and 216 species by comparing with the type specimens or original and subsequent descriptions. We here provide a preliminary list of Korean Tachinidae.

New records of genus *Hyphasis* (Coleoptera: Chrysomelidae: Alticinae) from Korea

Mi Hyun Kang[1], Jong Eun Lee[2]

[1]*Andong National University, Republic of Korea,* [2]*Andong National University, Republic of Korea*

The Alticine genus Hyphasis Harold, 1887 and a species of this genus H. parvula Jacoby, 1884 are recorded from Korea for the first time. The species of the genus Hyphasis Harold is distributed in the South eastern of Palearctic and Oriental region and more than 40 species were recorded in the world. The genus Hyphasis can be distinguished from the other genera by combination of following characteristics: pronotum without any ante-basal transverse impression; posterior tibia with a pointed spine at the apex; claw-segment of hind tarsus strongly dilated. The species H. parvula is easily distinguished from the published Hyphasis species by the following characters: body reddish brown; vertex impunctate, frontal ridge very thin and low anteriorly, slightly widened antennal calli; antennae blackish brown except for two basal segments, second segment shorter than third; elytra without a patch, epipleura extraordinarily broad, confusedly punctate.

Comparative analysis of *Dolichoderus sibiricus* Emery (Hymenoptera : Formicidae) between Korea and Japan

Eui Jeong Hong[1], Min Jee Kim[2], Ki-gyoung Kim[3], Iksoo Kim[4], Byung-jin Kim[5]

[1]Wonkwang University, Republic of Korea, [2]Chonnam National University, Republic of Korea, [3]National Institute of Biological Resources, Republic of Korea, [4]Chonnam National University, Republic of Korea, [5]Wonkwang University, Republic of Korea

We conducted a comparative analysis to know the intra-specific variations among Dolichoderus sibiricus Emery collected from Korea and Japan. The D. sibiricus collected from three Korean regions and one Japanese region (Hokkaido) were compared by morphological measurement and DNA sequence analysis of 658-bp of mitochondrial barcode region. The morphological measurements are as follows (mm): Japanese; AL 1.193, TL 3.885, CI 104.1, SI 81.85, EI 23.95, Cheongyang; AL 1.216, TL 4.015, CI 105.3, SI 80.97, EI 25.64, Hongcheon; AL 1.017, TL 3.609, CI 106.1, SI 82.1, EI 24.18 and Uijeongbu; AL 0.985, TL 3.228, CI 106.1, SI 80.9, EI 24.71. The morphological analysis has shown difference in the 4 Regions. Although specimens from Uijeongbu and Hongcheon were similar, those from Cheongyang were different. On the other hand, specimens from Japan and Cheongyang were similar, but the form of mesonotum and propodeum differ between them. The results of the COI analysis showed sequence variation, ranging from 0.15% (1 bp) to 8.2% (54 bp). The Korean specimens from three regions showed as large as 0.3%, whereas comparisons to Japanese specimens showed 8.2% (54 bp). These results collectively suggest that at least Korean and Japanese specimens differ to each other, indicating intra-specific variations between Korea and Japan. Considering current data were obtained from limited sample size further conclusive result can be obtained as more specimens are analyzed.

Taxonomic revision of the leafhopper genus *Macropsis* Lewis from Korea (Homoptera: Cicadellidae)

Jin Hyung Kwon[1], Yong Jung Kwon[2]

[1]*Kyungpook National University, Republic of Korea,* [2]*Kyungpook National University, Republic of Korea*

The genus Macropsis Lewis is revised taxonomically from Korea, primarily based on the abdominal apodemes, male genitalia, and 2nd valvulae of ovipositor. Previously only three species were erroneously recorded from Korea. Among them, Macropsis prasina (Boheman, 1852), has been misidentified with Macropsis notata (Prohaska, 1923) that is mentioned here. The other two species, Macropsis scutellata (Boheman, 1845) and Macropsis illota (Horvath, 1899), are declared absent in Korean fauna because of their superficial resemblance with allied species. A total of 7 species are recognized in this revision, among which six are new to science. All the species are described and illustrated, and identification key to species from Korea is provided.

A checklist of the collembolan species from Korea

Ji Sup Kwak[1], Sangkyu Kang[2], Kyung-Hwa PARK[3]

[1]Chonbuk National University, Republic of Korea, [2]Chonbuk National University, Republic of Korea, [3]Chonbuk National University, Republic of Korea

The Korean Peninsula is located between 33˚ and 43˚ north latitude, and 124˚ and 131˚ east longitude. Korea's total land area is 100,033 sq km including North Korea, and mountains cover 70% of Korea's land mass. The high mountain ranges with its complicated topographies, naturally, contain a variety of environments and include subtropical, temperate, alpine forests areas. Korea also has more 3,000 islands that surround the peninsula. As these complicated geography, the Korean Peninsula consists of several ecoregions. Collembola are small, primitive soil insects and their habitat varies greatly. They are ubiquitous, being found in all terrestrial biomes, including mountain tops, polar regions and deserts. As a result of its world-wide distribution, approximately 8000 species have been reported throughout the world (Janssens, 2012). The first recognizable Korean Collembolan species were two species listed by Kinoshita (1932): Tomocerus varius Folsom and Bourletiella hortensis Fitch. Many species of this group have been reported subsequently from the Korean Peninsula since then and now 255 species (including North Korean species) in 85 genera belonging to 18 different families are reported in Korea based on literature records.

A checklist of the Korean aquatic Collembola

Kyung-Hwa Park[1], Sangkyu Kang[2]

[1]Chonbuk National University, Republic of Korea, [2]Chonbuk National University, Republic of Korea

Waltz and McCafferty (1979) divided Collembola into three categories based on the relative degree of association and adaptation to the aquatic environment. Primary aquatic associates are those found exclusively in aquatic habitats; secondary aquatic associates are found in and around aquatic habitats, but a also inhabit other areas with high humidity and moisture; and tertiary aquatic associates, typical in part of the transitory neuston and inhabiting temporary pools formed by rain while having the least apparent adaptation to aquatic habitats. A number of systematic studies of hydrophilous Collembola on seashores and associated with freshwater have been carried out in North America, Japan, and several European countries. However, the Korean aquatic Collembolan fauna has still been very poorly investigated. The only report from Korean freshwater habitats was that of Kim and Lee (2000) listing ten species in nine genera, of which four species were new to science and six were new records for the Korean Peninsula. For our intensive study on halophilous Collembolan fauna in Korea, we scanned printed records and laboratory collections of collembolan species based on materials from freshwater. A total of 28 species in 19 genera belonging to 9 different families are reported in Korea.

Nematode identification of imported agricultural crops in plant quarantine of Republic of Korea

Dong Woo Kim[1], Jae-yong Chun[2]

[1]Animal, Plant and Fisheries Quarantine and Inspection Agency, Republic of Korea, [2]Animal, Plant and Fisheries Quarantine and Inspection Agency, Republic of Korea

Diagnosis of plant quarantine species is important in the process of the importation of the exotic plants and agricultural products from various foreign countries. There have been difficulties for the diagnosis of exact nematode species in plant quarantine due to the deficit of the information of exotic nematode identification. We obtained the information about morphological identification characteristics of exotic nematode species currently detected in plant quarantine inspection. Since 2006, nematode detection from imported agricultural crops and exotic plants was average 302 cases in every year. Newly identified species were 8 species belonging to 7 genus, 6 families including Anguina sp., Aphelenchoides haguei, Ditylenchus khani, Meloidogyne chitwoodi, Meloidogyne sp., Paraphelenchus acontioides, Rotylenchulus reniformids, and Rotylenchus arsenjevi. Both Anguina sp. and Meloidogyne sp. were unable to diagnose the exact species due to the deficit of the nematode number detected from the sample and the sources of relative literature. Both species were designated as the unrecorded species in Korea. We provided images, measured value and morphological characters of newly identified species in quarantine inspection.

A new species and two new records of the family Neanuridae from Korea

Pil Ja Park[1], Kyung-Hwa Park[2]

[1]Chonbuk National University, Republic of Korea, [2]Chonbuk National University, Republic of Korea

The family Neanuridae belongs to order Poduromorpha in class Collembola and approximately 1404 species in 171 genera have been known worldwide. It is over 6.37% of all described species of Collembola. However, only 75 species in 24 genera have been recorded from Korean peninsula. A new species of Pseudachorutes and two unrecorded species, Morulina pawlowskii, Lobella sokamensis, are recognized in Korea. The new species differs in the body chaetotaxy, the number of lobes of PAO, and the shape of mandible compare to relative species. Herein, a brief descriptions and diagnostic photographs/or figures of three Korean Neanurid species are presented with a taxonomic key of their genera for identification. The comparison of differentiating characters of all Pseudachorutes species from South Korea are given as well.

DNA barcode of arthropod pests from pine mushroom from Korea and imported

Kwang-su Lee[1], Heung-Sik Lee[2], Eun-Young Yoon[3], Cheonl-sun Ko[4]

[1]Animal Plant and Fisheries Quarantine and inspection Agency, Republic of Korea, [2]Animal Plant and Fisheries Quarantine and inspection Agency, Republic of Korea, [3]Animal Plant and Fisheries Quarantine and inspection Agency, Republic of Korea, [4]Animal Plant and Fisheries Quarantine and inspection Agency, Republic of Korea

This study was carried out for pest risk analysis of pine mushroom imported from China and North Korea, compariing pests from imported pine mushroom with from Korean pine mushroom. Pests of pine mushroom were usually found as immatual stage, so needed to rear them to adults. It was hard to identify larvae into species level, DNA BArcode (COI region of Mitochondria) from each species sample were compared, to confirm if they were same speceis or not. The number of arthropod species from pine mushroom in Korea was 149 samples, under 15 families 7 orders. The pests collected on surface of mushroom were 6 sepcies 6 families in Coleoptera, 2 species 1 family, Hymenoptera, 2 species 2 families, Diptera, 1 Thysanoptera, several Colembola, a mite, and a milipoda. The number of family of pest attacking on inner side of mushroom was 6 families of Diptera, according to DNA barcode analysis, 2 sepceis in Sciaridae, 10 in Drosophilidae, 4 Phoridae, 1 Mycetophilidae, 1 Tipulidae, and 1 Psychodidae were found. On the other hand, DNA barcodes of 4 species (2 in Phoridae, and 2 Drosophilidae) were acquired after analysis of seuencing of several fly samples inspected in pine mushroom from China. As a result of comparison of DNA barcodes, one species of Drosophilidae was coincide with Korean species, but the others were different from Korean.

Morphometrics of the final instar exuviae for four cicada species occurring in urban areas of central Korea

Hyung-Yun Lee[1], Seung-YoonOh Oh[2], Yikweon Jang[3]

[1]Ewha Womans University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Ewha Womans University, Republic of Korea

Cicadas that produce loud calling songs for mate attraction can be a nuisance to city dwellers in Korea. The exuviae of final instars can be used for estimation of population density. To provide a key for species identification, we investigated morphological characteristics of final instar exuviae for four cicada species that are abundant in urban areas of central Korea: Cryptotympana atrata, Meimuna opalifera, Oncotympana fuscata, and Graptopsaltria nigrofuscata. The characters analyzed were pro-mesonotum length, pronotum width, pronotum length, head width, mesonotum length, body length, wing length, and femoral tooth angle. The results of a general linear model showed that species and sex were significant for morphological characters, and the result of post hoc analyses revealed that the mean values of most of the morphological characters measured were significantly different among four cicada species. C. atrata and M. opalifera were separated from the other species in most characters measured. Although O. fuscata and G. nigrofuscata were not distinguishable based on size-related characters, these two species differed in femoral tooth angle. Therefore, the exuviae of all four cicada species can be easily distinguished based on the morphological characters used in this study.

Keywords:*Cryptotympana atrata, exuvia, Graptopsaltria nigrofuscata, Meimuna opalifera, Oncotympana fuscata*

A new species of the genus *Adoxophyes* (Lepidoptera: Tortricidae) on the sweet cherry imported from China under the plant quarantine in Korea

Deuk-Soo Choi[1], Young Mi Park[2], Jungyoun Ji[3], Bong-Kyu Byun[4]

[1]Animal, Plant and Fisheries Quarantine and Inspection Agency (QIA), Republic of Korea, [2]Animal, Plant and Fisheries Quarantine and Inspection Agency (QIA), Republic of Korea, [3]Animal, Plant and Fisheries Quarantine and Inspection Agency (QIA), Republic of Korea, [4]Hannam University, Republic of Korea

A new species, Adoxophyes cerasus Park, is described, illustrated, and distinguished from closely resembling species. Larvae of this species were discovered on sweet cherry (Prunus avium) imported from China and intercepted under plant quarantine inspection at Korean sea- and airport in 2008. They were reared to adult in the laboratory for identification. We also collected a male specimen from China for this study. We provide a full description of the new species based on adult of external structures. In addition, we conducted a comparative study of three related species (A. orana, A. hanmai, and A. paraorana) and provided a key to distinguish them. To confirm the identity of new species, we compared DNA barcoding sequences (658 bp) of the mitochondrial cytochrome c oxidase subunit I (COI) gene from 13 specimens of four Adoxophyes species. As a result of this study, we confirmed the identity of Adoxophyes new species. We also provided pairwise p-distances among the species and their neighbor-joining tree.

Xyleborini Ambrosia Beetles of Melanesia: Taxonomic revision and monograph

Jiri Hulcr[1], Anthony I. Cognato[2]

[1]*University of Florida, U.S.A.*, [2]*Michigan State University, U.S.A.*

We revised the genera and species of Xyleborini (Coleoptera, Curculionidae: Scolytinae) recorded from New Guinea and neighboring islands. We examined over 44,000 representatives of 281 species, including 264 type specimens. The classification used here was based on the Catalog of Scolytidae and Platypodidae (Wood & Bright, 1992, Bright & Skidmore, 1997, 2002), and several recent cladistic and molecular analyses of Xyleborini. Morphological characters inferred by these analyses as phylogenetically informative were used to define genera and species. Many previously described species were found to be delimited by uninformative characters, 59 such species are synonymized. Three new genera are defined (Ancipitis, Immanus, Stictodex), and 20 new combinations are given. The monograph is complemented by photographs of all species and multiple-choice electronic keys to all species and genera, both available on-line. Because all the genera and many species occurring in New Guinea also occur throughout the Eastern Paleotropic region, the presented re-classification is significant for Xyleborini taxonomy on much larger geographical scale, in many cases for world-wide classification.

Open the gates to the diversity of Protura

Carol Resch[1], Gerald Timelthaler[2], Nikolaus Urban Szucsich[3], Daniela Bartel[4], Guenther Pass[5]

[1]University of Vienna, Austria, [2]University of Vienna, Austria, [3]University of Vienna, Austria, [4]University of Vienna, Austria, [5]University of Vienna, Austria

Protura are small entognathous hexapods living in the soil. The hidden life style is but one reason why this group has proven difficult to be studied. Challenges start at the very beginning of every scientific approach. Due to their small size and due to the lack of conspicuous characters, species determination is a rare skill, restricted to a handful of scientists. The minuteness of Protura, along with the difficulties to determine specimens to species level makes sampling a hard task. Then again Protura are among the oldest lineages of hexapods, and thus indispensable to understand the evolution of the most diverse animal group on earth. Aim of our study was to address proturan diversity by sequencing the barcoding region of the CO I gene and a fragment of the 28S rRNA. The study was triggered by the close vicinity of our university to the biodiversity hotspot of Protura. In 2004 Christian and Szeptycki mentioned 23 proturan species to occur syntopically in the outskirts of the city of Vienna. Standard protocols and primers had to be modified in order to be applicable for proturans. We used a non-destructive method of DNA extraction, which leaves the cuticle intact for further morphological analyses (e.g. CLSM). Methods will be presented, along with first results on the molecular diversity of Austrian Protura.

Real-time tracing of AcMNPV infection to *Plutella xylostella* and the interaction between virus and parasitoid

Shu-Jen Tuan[1], Roger F. Hou[2], Suey-Sheng Kao[3]

[1]National Chung Hsing University, Taiwan, [2]National Chung Hsing University, Taiwan, [3]Taiwan Agricultural Chemicals and Toxic Substances Research Institute, Taiwan

Baculovirus is an important microorganism for controlling insect pests in the field, and is also crucial for integrating into an ecologically sound IPM program. In order to trace baculovirus infection, a recombinant baculovirus, vAcGFP, derived from Autographa californica nucleopolyhedrovirus (AcMNPV) was constructed. This virus contains a wt polyhedrin gene and a GFP coding region driven by p10 promoter. The LC50 values of vAcGFP and wt AcMNPV to the 3rd instar larvae with the diet incorporation method were 34.4 and 25.6 OBs/mm3 of diet, respectively. The LT50 values of these two viruses were relatively close. The larvae infected with vAcGFP were easily detectable due to the emittion of green fluorescence (505nm) as irradiated by a 365nm UV light. Its FT50 (50% fluorescense-emitting time) was 65 h earlier than LT50 at 763 OBs/mm3. The 3rd instar larvae of P. xylostella were inoculated with vAcGFP and simultaneously parasitized by the parasitoid, Cotesia plutellae. A fluorescence-emitting rate of 84 and 32% was separately coupled with 12 and 54% cocooning rate at 76.3 and 7.6 PIBs/mm3, respectively, and only 5~8% cocoons with fluorescence was detected. The cocooning rate of C. plutellae was decreasing through the time of parasitism and the increasing of viral concentration. In conclusion, GFP could be used as a specific and non-destroying biomarker for detection of insect dynamics after being infected with NPV in the field. In addition, our study shed a light for further study of the complicated interactions between baculovirus and broconid wasp in an insect host.

New record for the Turkish house fly (Muscidae: Diptera) fauna

Cenk Onsoy[1], Ferhat Altunsoy[2]

[1]Anadolu University, Turkey, [2]Anadolu University, Turkey

The Muscidae one of the largest family of the calyptrate Diptera that contains almost 4500 described species over 86 genera. The world-widespread distributed Muscidae is presented within approximatelly 620 species in Europe and it constitutes a large portion of Diptera fauna on the country. This work provides the first country record for the species extending the known range of the species and taxonomic characters were given in details.As a result of many researches, the Muscidae, forensically third important family is dedicated as significant on forensic cases. In this study, specimens of Mesembrina meridiana (Linnaeus 1758) which is a new record for the Turkish fauna, were collected on different days of pig decomposition during a forensic entomology research, in Eskisehir. The specimens were collected on 3th and 8th days of decomposition, fresh and bloat stages when Calliphoridae and Sarcophagidae species not certainly active due to seasonal activity periods. The preferred habitat of this species, ovulation activity zone preference, and availability for forensic investigations briefly discussed in this study.

Determination of the phylogeny of some tabanidae (Diptera : Tabanidae) species using coi gene area

Ali Yavuz Kilic[1], Sukran Yalcin[2]

[1]Anadolu University, Turkey, [2]Anadolu University, Turkey

The Tabanidae Bromius group (Insecta: Diptera) members had been tried to identfy from their universal gene areas. Specimens were collected from different areas of Turkey Collected specimens' cytochrome oxidase one gene area were amplified with one of the universal primer COI, through polymerase chain reaction and had done sequencing. Achieved sequences analysed with MEGA5 program, BOLDsystems, Kimura 2 parameter and General Time Reversible Gamma disribution model comparing genebank sequences, than had got phylogenetic trees using Neighbor joining and Maximum Likelihood statistical methods. Based on the results obtained from phylogenetic trees the group members are geographically divided into 7-8 groups in their species group which proved their different populations. According to analysis results that are difficult to distinguish morphologically from each other, T. maculicornis, T. miki and T. armeniacus bootstrap value of 90% shared same klad on the trees. Nearest-Neighbor-Interchange method gives optimal trees of the results. According to the these optimal trees Neighbor joining and Maximum likelihood trees figure in attachment-4 specimens' sequences results are divided into two groups and the trees do not include any gene bank specimen. In fact, there are not any documented data about Bromius group specimen from Turkey at the gene bank, so comparing is not possible. Because of that, this study is very important including first data about bromius genes from Turkey. According to numerous analysis it is obvious that difficult to distinguish morphologically from each other, T. maculicornis, T. miki and T. armeniacus shared same klad a very high bootstrap value of 90%.

Occurrence of grape rust mite, *Calepitrimerus vitis*, in Korea

Myoung Rae Cho[1], Jong Ho Lee[2], Taek Jun Kang[3], Hyung Hwan Kim[4], Seung Joon Ahn[5], Seung Wook Jeon[6], Hae Woong Park[7]

[1]National Institute of Horticultural and Herbal Science, Republic of Korea, [2]National Veterinary Research and Quarantine Service, Republic of Korea, [3]National Institute of Horticultural and Herbal Science, Republic of Korea, [4]National Institute of Horticultural and Herbal Science, Republic of Korea, [5]National Institute of Horticultural and Herbal Science, Republic of Korea, [6]National Institute of Horticultural and Herbal Science, Republic of Korea, [7]National Institute of Horticultural and Herbal Science, Republic of Korea

Grape rust mite, Calepitrimerus vitis, is one of the major pests in the vineyards in the world. The mite was recently found in grape farms and the taxonomic characteristics and the distribution are reprted for the first time in Korea. The female morpholgy are : Body fusiform, 170-190 long, 50-52 wide. Gnathosoma directed down, 20-25 long. Prodorsal shield broadly triangular, 33-36 long, 38-43 wide; frontal lobe overhanging gnathosoma, bilobed; prodorsal shield with median and admedian lines and granular lateral lines; dorsal tubercles ahead of rear margin; setae directed up and centrad. Dorsal annuli 67-72, slightly less than ventral annuli, 70-74, terminal annuli 5; three-fourths of dorsal annuli with middorsal ridge; dorsal annuli lobed dorsally and with faint, elongate, rounded microtubercles touching rear annular margins laterally. Ventral annuli with small rounded microtubercles touching rear annular margins. Setae h1 present, 5 long. Coverflap with 2-3 transverse granular lines basally, 10-12 longitudinal ridges, setae 13-14 long. Coxae with granulation, sternal line simple and faint. Empodia 5-rayed; tarsal solenidia knobbed. The damage symptom in greenhouse grape was delayed growth of new leaves and flowers. A survey on some major grape production area revealed that the mite is distributed in Hwasung, Ansung, Gapyung, Chunan, Okchun, Jeonju, Kimje and Kimchun. In the twig sample collected from the areas, the mite was found in the surface and ovewintering buds.

Taxonomic review of the genus *Zeiraphera* (Lepidoptera, Tortricidae) in Korea

Bong-Kyu Byun[1], Sat-Byul Shin[2]

[1]*Hannam University, Republic of Korea,* [2]*Hannam University, Republic of Korea*

The genus Zeiraphera belongs to the tribe Eucosmini belonging to the family Tortricidae, comprising more than 1,600 described species worldwidely (Brown, 2005). In Korea, totally six species have been listed by Byun et al (2009). Recently Byun (2011) added a species Zeiraphera lariciana Kawabe, 1980 from North Korea. In the present study, we review the genus Zeiraphera in the Korean peninsula. Also, the North Korean fauna for the genus is noted, based on the material of Hungarian Natural History Museum, Budapest, Hungary. In this study, a total of seven species is recognized from Korea with description of a new species and new faunistic data. All the known species is enumerated with illustration of their adult, male and female genitalia. A taxonomic list of the genus is as follows. Genus Zeiraphera Treitschke, 1829 1. Zeiraphera demutana (Walsingham, 1900) 2. Zeiraphera fulvomixtana Kawabe, 1974 3. Zeiraphera griseana (Hubner), 1799 4. Zeiraphera rufimitrana (Herrich-Schaffer, 1847) 5. Zeiraphera virinea Falkovitsh, 1965 6. Zeiraphera lariciana Kawabe, 1980 7. Zeiraphera paravirinea sp. nov.

A preliminary checklist of the family Psychidae(Lepidoptera) in Korea

Bong-Kyu Byun[1], Seung-Jin Roh[2]

[1]Hannam University, Republic of Korea, [2]Hannam University, Republic of Korea

The family Psychidae, so- called bagworms, of Korea is reviewed. A total of 1324 species of the family Psychidae have been described in the world to date (Sobczyk, 2002). However, the Psychidae of Korea has been poorly studied to date, including only 7 recorded species (Park et al., 1983; Byun et al., 2009.). In the present study, we reviewed and made a preliminary list of Korean Psychidae with their taxonomic illustration and available information, including locality, host plant and biological characteristics. Family Psychidae Boisduval, 1828 1.Mahasena aurea (Butler), 1881, Trans. Ent. Soc. London 1991: 23. 2.Eumeta japonica Heylerts, 1884, Annl. Soc. Ent. Belg. 28, Compt. Rend.: 11. 3.Eumeta minuscula Butler, 1881, Trans. Ent. Soc. London, 1881: 22. 4.Acanthopsyche nigraplaga Wileman, 1911, Trans. Ent. Soc. Historical review of Gracillariidae (Lepidoptera) in Korea

Bong-Kyu Byun[1], Young-Min Shin[2]

[1]Hannam University, Republic of Korea, [2]Hannam University, Republic of Korea

The family Gracillariidae has been known as a typical leaf-miners, with more than 2,300 described species in the world (Prins & Prins, 2005). In Korea, the first report on the familiy was made by Kumata et Park (1978) with description of a new species of the genus Phyllonorycter Hubner from Korea. Later thirteen species of three genera of the subfamily Lithocolletinea are reported from Korea (Kumata et al 1983). Park (1983) provided the checklist on this group of Korea with 26 species. Then, Park and Han (1986) reported six newly reported species with a list of thirty-six species of Gracillariidae in Korea. Park (1994) listed 38 species of the family. Recently forty-five species were enumerated in "A Checklist of the Microlepidoptera in Korea" (Byun et al., 2009). This study is aimed to review and clarify the fauna of the family Gracillariidae with available information. In the present study, a total of 45 species of 12 genera under two subfamilies are listed with taxonomic information including their collecting locality, host plant, and distributional range. Also a taxonomic key is provided.

Efficacy of DNA barcodes to identify insect foreign material in foods: A case study using tenebrionids (Coleoptera: Tenebrionidae)

Seo Young Cho[1], Boo Hee Jung[2], Kyong In Suh[3], Yeon Jae Bae[4]

[1]Korea University, Republic of Korea, [2]Yeungnam University, Republic of Korea, [3]Korea University, Republic of Korea, [4]Korea University, Republic of Korea

Insect pests that are found in food are of great economic and hygienic significance. However, the precise identification of each of these species often requires an expert taxonomist, and the process can be time-consuming. Furthermore, these pests are usually discovered in food in various conditions such as in terms of body parts or immature specimens; this further complicates the identification process. For these reasons, an efficient means of identification is necessary for developing a control scheme for insect pests. In this study, we tested the efficacy of DNA barcodes to identify tenebrionid beetles and other significant food pest species. Species-level identification based on external morphology can be difficult because these pests are extremely variable in body-size and form, as well as in terms of genetic polymorphisms. Furthermore, larvae of this species have also remained uncharacterized. The 640-bp cytochrome c oxidase subunit I (COI) gene in the tenebrionid mitochondrial DNA was sequenced and analyzed for variations in inter- and intra-species COI sequence. The effectiveness of the COI?based DNA barcodes in discriminating Korean tenebrionids through integrative re-examinations with over 20 unidentified species was also examined. Pairwise sequence divergence was calculated using the Kimura two-parameter model, and a neighbor-joining tree based on calculated generic differences among and within species was constructed.

Development of species-specific primers for the molecular diagnosis of quarantine species in the genus *Tetranychus* and *Amphitetranychus* (Acari: Tetranychidae)

Tin Moe Khaing[1], Jae Kyeong Shim[2], Jong Ho Lee[3], Won Goo Lee[4], Kyeong Yeoll Lee[5]

[1]Kyungpook National University, Republic of Korea, [2]Kyungpook National University, Republic of Korea, [3]Animal, Plant and Fisheries Quarantine and Inspection Agency, Republic of Korea, [4]Chonbuk National University, Republic of Korea, [5]Kyungpook National University, Republic of Korea

Spider mites are one of the most important mite pests of agriculture crops and also important in plant quarantine service. Morphological identification of mites can be difficult due to their small size and a few characters available and also lack of noticeable characters for immature mites. To overcome these difficulties, morphologically identified mites were compared with those of DNA sequences using internal transcribed spacer 2 (ITS2). Species-specific primers were designed according to the ITS2 sequences of 6 species in the genus Tetranychus (T. urticae, T. kanzawai, T. phaselus, T. truncatus,) and Amphitetranychus (A. quercivorus, A. viennensis) which are important in plant quarantine. Our results provide information for the accurate diagnosis of mite identification in plant quarantine.

Identification of biotypes and secondary endosymbionts of *Bemisia tabaci* in Korea and relationships with the occurrence of TYLCV disease

S. M. Hemayet Jahan[1], Jungan Park[2], Hong-Soo Choi[3], Kwan-Suk Lee[4], Chang-Suk Kim[5], Sukchan Lee[6], Kyeong-Yeoll Lee[7]

[1]Kyungpook National University, Republic of Korea, [2]Sungkyunkwan University, Republic of Korea, [3]National Institutes of Agricultural Science, Republic of Korea, [4]National Institutes of Agricultural Science, Republic of Korea, [5]National Institutes of Agricultural Science, Republic of Korea, [6]Sungkyunkwan University, Suwon, Republic of Korea, [7]Kyungpook National University, Republic of Korea

Bemisia tabaci is a species complex that consists of at least 24 genetically diverse biotypes. Here, we determined the biotypes of 27 populations collected in 17 different regions of Korea. Nucleotide sequence comparisons of cytochrome oxidase showed that 26 populations were Q biotype and that one population, the Goyang population, was B biotype. Further subgroup analysis of the Q biotype showed that all populations belonged to the Q1 subgroup, which originates from Western Mediterranean countries. Five endosymbiotic bacteria from various B. tabaci populations were analysed by comparing rDNA sequences. Hamiltonella was detected in all the populations tested regardless of biotype. Cardinium was detected in all Q biotype populations but not in the B biotype population, while Rickettsia was detected in the B biotype population but not in Q biotype populations. Arsenophonus and Wolbachia were detected in 35% and 58% of Q biotype populations, respectively, but not in the B biotype population. Our results show that the endosymbiont profile is strongly associated with each biotype and with subgroups of the Q biotype. Survey of TYLCV disease from 2008 to 2010 indicated that this disease is widely spread in Korea. This study suggests that the rapid spread of TYLCV may be associated with endosymbiont infection, particularly Hamiltonella infection of B. tabaci.

Molecular identification of spiraling whitefly *Aleurodicus dispersus* (Hemiptera: Aleyrodidae) and prevalence of secondary endosymbionts

S. M. Hemayet Jahan[1], Kwan-Suk Lee[2], Sukchan Lee[3], Kyeong-Yeoll Lee[4]

[1]*Kyungpook National University, Republic of Korea,* [2]*National Institutes of Agricultural Science, Republic of Korea,*
[3]*Sungkyunkwan University, Suwon 440-746, Republic of Korea,* [4]*Kyungpook National University, Republic of Korea*

Spiraling whitefly, Aleurodicus dispersus, is a serious pest in tropical and neotropical regions especially for south-east Asia and also important in plant quarantine. In Bangladesh, Myanmar and Philippines its damage has been devastated in fruits and ornamental plants particularly for guava. Here, we conducted molecular identification of the spiraling whiteflies collected from Bangladesh, Myanmar and Philippines. Nucleotide sequence comparisons of both mitochondrial cytochrome oxidase I (mtCOI) and 16S ribosomal RNA (16S rRNA) showed that mtCOI and 16S rRNA was most simliar to Aleurodicus dugesii and A. dugesii at rates of 90% and 91%, respectively. We designed a mtCOI specific primer set of A. dispersus for the species diagnosis of in plant quarantine. In addition, we conducted the identification of secondary endosymbionts from different populations of A. dispersus by the PCR analysis using primer sets of 16-23S rDNA sequences that can be used for the endosymbiont identification of Bemisia tabaci. Wolbachia was detected in all the tested populations. Cardinium was detected in populations of Myanmar and Philippines but not in that of Bangladesh. However, spiraling whiteflies were never be infected with Arsenophonus, Hamiltonella and Rickettsia. Both Wolbachia and Cardinium of A. dispersus was highly similar to those of Wolbachia (Cinara cedri at rates of 99% in Myanmar, Diaphorina citri at 100% in Bangladesh, and Naupactus cervinus at 99% in Philippines) and Cardinium (Encarsia berlesei at rates of 99% in Philippines and Bemisia tabaci at 92% in Myanmar) respectively. Our results show that the endosymbiont profile is strongly associated with the species

Phylogenetic relationships of the insect order Odonata using COI, 16S rRNA, 28S rRNA and EF1-α Sequences

Minjee Kim[1], Kwang Soo Jung[2], Ki-Gyoung Kim[3], Joong Won Park[4], Ju Young Lee[5], Jumin Jun[6], IKSOO KIM[7]

[1]Chonnam National University, Republic of Korea, [2]Andong National University, Republic of Korea, [3]National Institute of Biological Resources, Republic of Korea, [4]Chonnam National University, Republic of Korea, [5]Chonnam National University, Republic of Korea, [6]National Institute of Biological Resources, Republic of Korea, [7]Chonnam National University, Republic of Korea

A diverse phylogenetic relationship has been proposed at several taxonomic levels for the insect order Odonata both by morphological and molecular data. This includes the non monophyleties of each suborder Zygoptera and Anisoptera, and variable relationships among superfamilies and families. In this study, approximately 3,800 nucleotide sequences from 2 mitochondrial genes (cytochrome oxidase subunit I, COI and 16S ribosomal RNA, 16S rRNA) and 2 nuclear genes (28S rRNA and elongation factor-1 alpha, EF-1α) were sequenced from 70 species of Odonata occurring in Korean peninsula (9 families, 6 superfamilies, and 2 suborders), along with 4 outgroup species (each one species from Hemiptera and Orthoptera, and two from Ephemeroptera). These sequences were subjected to phylogenetic reconstruction via Bayesian Inference (BI), Maximum Likelihood (ML), and Maximum Parsimony (MP) algorithms. In all analysis, each families and superfamilies were all consistently clustered together as monophyletic groups with a high nodal support, whereas majority of analyses placed the Lestidae belonging to Zygoptera as the most basal lineage of Anisoptera, suggesting the possibility of non monophyly of the suborder Zygoptera. Topological test to find out better supported tree further strongly supported non monophyly of Zygoptera, providing higher statistical estimates. Further scrutinized analyses will be performed to obtain further robust phylogenetic relationships.

Taxonomic revision of the genus *Chionea* Dalman (Diptera: Limoniidae) in Korea

Yong Jung Kwon[1], Sang Jae Suh[2]

[1]*Kyungpook National University, Republic of Korea,* [2]*Kyungpook National University, Republic of Korea*

Snow crane flies of the genus Chionea are characterized by the complete reduction of their wings and by the winter activity of adults. Although they are distributed over the Holarctic region, so far only seven species are known to come from Far East Asia: Chonea araneoides Dalman, C. kanenoi Sasakawa, C. crassipes crassipes Boheman, C. crassipes magadanensis Narchuk, C. nipponica Alexander, C. pusilla Savchenko and C. mirabilis Vanin. As far as we know, the first record of the genus from Korea was made by Savchenko (1992), who reported Chionea crassipes gracilistyla (= C. crassipes) from North Korea. Thereafter, Vanin (2008) described a new species, C. mirabilis, from Mt. Deogyusan (500-600m), in the southern region of the South Korea with the record of C. crassipes. Therefore, only two species have been known to Korean fauna. In this paper, a total of three Korean species of the genus Chionea are treated. Among them, C. kanenoi Sasakawa, 1986 is recorded for the first time in Korea.

A revision of the Aulacidae (Hymenoptera: Evanioidea) with two new species from Korea

Jin-Kyung Choi[1], Jong-Wook Lee[2]

[1]National Institute of Environmental Research, Republic of Korea, [2]Yeungnam University, Republic of Korea

The family Aulacidae currently includes 240 extant species placed in three genera: Aulacus Jurine, 1807 (76 species), Pristaulacus Kieffer, 1900 (164 species), and Panaulix Benoit, 1984 (2 species). Members of this family are distribute in all zoogeographic regions except Antarctica (Kieffer 1912; Hedicke 1939; Benoit 1984; Smith 2001, 2005a,b, 2008; He et al. 2002; Jennings et al. 2004a,b,c; Turrii 2004, 2005, 2006, 2007, 2011a,b; Jennings & Austin 2006; Sun & Sheng 2007a,b; Lee & Turrisi 2008). Recent reports (Konishi 1990; Mason 1993; Gauld 1995) recognized Aulacidae as a distinct family among the Evanioidea, and not a subfamily of the Gasteruptiidae, as reported by some authors (e.g. Rasnitsyn 1988). Also, Jennings and Austin (2000) and Turrisi (2004) provided evidence for a monophyly of the Aulacidae, based upon cladistic analysis. This family is parasitoids of wood-boring Hymenoptera and Coleoptera, and they use a koinobiont endophagous strategy (Skinner & Thompson 1960; Whitfield 1998; Jennings & Austin 2004). In this study, we report the family Aulacidae with two new species, Pristaulacus n. sp. candidate 1 and Pristaulacus n. sp. candidate 2. Including the two new species, the number of Korean Aulacidae is now seven: Aulacus salicius Sun and Sheng, 2007, Pristaulacus insularis Konishi, 1990, P. intermedius Uchida, 1932, P. kostylevi Alekseev, 1986, P. jirisani Smith and Tripotin, 2011, P. n. sp. candidate 1, and P. n. sp. candidate 2. A detailed descriptions, figures of morphological features, and a key to the Korean Aulacidae are provided.

Descripion of immature stages of *Tipula(Nippotipula) coquilletti* (Insecta, Diptera, Tipulidae) from Korea with notes its ecology

Jaeick Jo[1], Dongsoo Kong[2]

[1]Kyonggi University, Republic of Korea, [2]Kyonggi University, Republic of Korea

The external anatomy of the last instar larva and pupa of the crane fly, Tipula(Nippotipula) coquilletti Enderlein, 1912 (Diptera: Tipulidae), is described and illustrated from specimens collected in Korea. Comments concerning natural history and microhabitats of larvae are provided. This is the first detailed description with illustrations for the larva and pupa of Tipula(Nippotipula) coquilletti. Pupal characters resemble those of most species from advanced lineages within the subfamily Tipulinae.

Molecular phylogeny and estimates of divergence times of Nymphalidae (Lepidoptera: Papilionoidea) based on concatenated mitochondrial and nuclear genes

Xinlong Wan[1], Min Jee Kim[2], Iksoo Kim[3]

[1]Chonnam National University, Republic of Korea, [2]Chonnam National University, Republic of Korea, [3]Chonnam National University, Republic of Korea

The phylogenetic relationships among the Nymphalidae (Lepidoptera: Papilionoidea) have been controversial in several perspective. The present study sequenced a total of ~ 3,404 bp from cytochrome oxidase subunit I (COI), 16S ribosomal RNA (16S rRNA), and elongation factor-1 alpha (EF-1α) in 80 nymphalid species belonging to seven subfamilies (Linmenitidinae, Heliconiinae, Nymphalinae, Apaturinae, Libytheinae, Satyrinae, and Danainae), along with those of six species of Pieridae as outgroups. Phylogenetic analyses consistently supported the subfamilial relationships of (((((Linmenitidinae + Heliconiinae) + (Nymphalinae + Apaturinae)) + Satyrinae) + Libytheinae) + Danainae), with a high nodal support for monophyletic subfamilies and tribes. This result is largely consistent with a previous study performed with substantially large sequence information and morphological characters, but the positions of Libytheinae and Danainae are exchanged. For the relationships among genera within subgroups of Nymphalidae, Coenonympha was consistently placed as the basal lineage of the Satyrii with strong supports. In tribe Argynnini, the genus Argynnis was supported monophyletic and sister to Brenthis. The genus Aldania always was included in the group of Neptis within tribe Neptini, resulting in Neptis non-monophyletic, which is probably related to the origin of Aldania. The analysis of divergence times among subfamilies suggests that Nymphalidae began diversifying at around 96 million years ago (MYA), with Danainae branching off the common ancestor of the rest of Nymphalidae. The remaining subfamilies diverged between 62.16 MYA and 89.56 MYA, suggesting that all subfamilies in Nymphalidae have diverged in late Cretaceous or within short time after Tertiary.

Complete mitochondrial genome of the free-living earwig, *Challia fletcheri* (Dermaptera: Pygidicranidae) and phylogeny of Polyneoptera

Xinlong Wan[1], Min Jee Kim[2], Iksoo Kim[3]

[1]Chonnam National University, Republic of Korea, [2]Chonnam National University, Republic of Korea, [3]Chonnam National University, Republic of Korea

The insect order Dermaptera, belonging to Polyneoptera, includes ~2,000 extant species, but no dermapteran mitochondrial genome has been sequenced. We sequenced the complete mitochondrial genome of the free-living earwig, Challia fletcheri, compared its genomic features to other available mitochondrial sequences from polyneopterous insects. In addition, the Dermaptera, together with the other known polyneopteran mitochondrial genome sequences (protein coding, ribosomal RNA, and transfer RNA genes), were employed to understand the phylogeny of Polyneoptera, one of the least resolved insect phylogenies, with emphasis on the placement of Dermaptera. The complete mitochondrial genome of C. fletcheri presents the following several unusual features: the longest size in insects is 20,456 bp; it harbors the largest tandem repeat units (TRU) among insects; it displays T- and G-skewness on the major strand and A- and C-skewness on the minor strand, which is a reversal of the general pattern found in most insect mitochondrial genomes, and it possesses a unique gene arrangement characterized by a series of gene translocations and/or inversions. The reversal pattern of skewness is explained in terms of inversion of replication origin. The markedly different gene arrangement of C. fletcheri is hypothesized to be due to some unique organism-level properties which allow relaxed selection against mitochondrial gene rearrangement. All phylogenetic analyses consistently placed Dermaptera as the sister to Plecoptera, leaving them as the most basal lineage of Polyneoptera or sister to Ephemeroptera, and placed Odonata consistently as the most basal lineage of the Pterygota.

A taxonomic study on the Genus *Linnaemya* Robineau-Desvoidy (Diptera, Tachinidae) in South Korea

Jong-Su Lim[1], Il-Kwon Kim[2], Ho-Yeon Han[3]

[1]Korea National Arboretum, Republic of Korea, [2]Korea National Arboretum, Republic of Korea, [3]Yonsei University, Republic of Korea

Robineau-Desvoidy (1830) erected the genus Linnaemya based on the type-species, L. silvestris Robineau-Desvoidy. The world fauna of the genus currently includes 149 nominal species, including 51 Palaearctic, 42 Oriental, seven Nearctic, five Australian, and 64 Afrotropical species. Only three species were known from South Korea up to date. They are charaterized as follows: 1) parafacials bare with normally three sternopleural setae, 1+3 intra-alar setae; 2) epistome prominent but not strikingly nasute; 3) vibrissae inserted above the level of the epistomal margin by a distance less than the length of the second antennal segment; and 4) posternal membrane and prosternum bare. As the result of the present study, I recognize one possible new species and seven new records have been recognized from South Korea. In addition, morphological phylogenetic analyses were conducted to infer interspecific relationships among Linnaemya species using species of the genus Lypha as an outgroup.

Vietnam is located on the eastern Indochina Peninsula between the latitudes 8° and 24° N, and the longitudes 102° and 110° E. It covers a total area of approximately 331,210 square kilometers (127,881 sq mi), excluding the Hoang Sa and Truong Sa islands, making it almost the size of Germany. The combined length of the country's land boundaries is 4,639 kilometers (2,883 mi). During the winter or dry season, extending roughly from November to April, the monsoon winds usually blow from the northeast along the China coast and across the Gulf of Tonkin, picking up considerable moisture. Temperatures vary less in the southern plains around Ho Chi Minh City and the Mekong Delta, ranging between 21 and 28 °C (69.8 and 82.4 °F) over the course of a year. Seasonal variations in the mountains and plateaus and in the north are much more dramatic, with temperatures varying from 5 °C (41 °F) in December and January to 37 °C (98.6 °F) in July and August. This expedition was conducted two times in two years (2003, 2004). Sweeping method, light trap and searching etc., were used to collect insect. Up to now, 35 species of 4 families(Nymphalidae, Pieridae, Papilionidae, Lycaenidae) were confirmed. Collected species, collecting sites, collecting method, collected specimens, ecological notes and activities of Vietnam will present with photos.

The insect fauna of Dokdo

Yong Kyun Oh[1], Jinyoung Park[2], Ik Je Choi[3], Eun Young Choi[4], Jong Kyun Park[5]

[1]Kyungpook National University, Republic of Korea, [2]Kyungpook National University, Republic of Korea, [3]Kyungpook National University, Republic of Korea, [4]Kyungpook National University, Republic of Korea, [5]Kyungpook National University, Republic of Korea

Dokdo is an island situated in the east longitude 131° 52′ and the north latitude 37° 14′. The full address for Dokdo is: 1-37 mountains, Dokdo-ri, Uleung-eup, Uleung-gun, Gyeongsangbuk-do, South Korea also the islets are located in the sea area 90 km southeast to Uleungdo and east of the Korean Peninsula. Dokdo is consisted of 2 main islands called Dongdo and Seodo and 33 attached small rocks and reefs. The gross area is 186,121㎡. Dokdo is important to migratory bird because it is on the migratory bird's flyway. Insect Fauna of Dokdo is researched intermittently and incompletely. However, it is very significant geographical, economical and militarily. The important value was recognized culturally and it have been many investigations later 2000. As a result 132 species belonging to 129 genera of 65 families in 11 orders recorded in Dokdo from 2010~2011 by our research. Species list photo of main specimens and historical records etc. are provided here in.

Newly recorded family Heliozelidae from Korea

Bong-Woo Lee[1], Shin-Young Park[2], Bong-Kyu Byun[3]

[1]Korea National Arboretum, Republic of Korea, [2]Korea National Arboretum, Republic of Korea, [3]Hannam University, Republic of Korea

The family Heliozelidae includes very small-sized moths with forewing length of 3-9mm, comprising 12 genera and about 100 species in the world. It has a worldwide distribution mainly in the Nearctic and Australian regions, but it has not been known from Korea. The adults of Heliozelidae are seldom collected, because of their small size and diurnal habit. In addition, this family is leaf miner through the larval stage and it has single generation for the year. Heliozelidae lacks cross-vein M-CuA on the hindwing. It is principle autapomorphic character for the family. The larvae of almost genera are known to mine in a leaf of trees and shrubs of Myrtaceae, Vitaceae, Cornaceae, Fagaceae, Saxifragaceae, etc., except only one genus, Antispilina Hering, 1941, which is known to mine in herbaceous plants. Recently, participating in a research project of Korea National Arboretum, we collected several heliozelid species, Antispila hikosana, A. purplella, Heliozela limbata and so on, in Korea. In the present study, male and female genitalia, abdomen of adults are described.

Confirmation of the fifth mitochondrial DNA lineage of the western honeybee from Sudan

Mogbel Ahmed Abdalla El-Niweiri[1], Elhadi Adam Omer[2], Robin Moritz[3]

[1]National Centre for Research (NCR), Sudan, [2]Juba University, Sudan, [3]Martin-Luther University of Halle-Wittenberg, Germany

Using mtDNA variability, the Apis mellifera subspecies could be classified into five major lineages: 1) lineage A including A. m. intermissa, A. m. adansonii, A. m. scutellata, A. m. capensis and A. m. monticola subspecies; 2) lineage M composed of the western European subspecies A. m. mellifera and A. iberiensis ;3) lineage C composed of A. m. ligustica, A. m. carnica and A. m. caucasica ;4) lineage O comprising A. syriaca and A. lamarckii; 5) lineage Y with A.m jemenitica. Apis mellifera jemenitica occupied a large area extend from Mali in west Africa through Sudan to the Arabian peninsula in Asia. However its classification is still controversial in morphometrical as well as genetic studies. The Y lineage which had recently been classified in A. m. jemenitica of Ethiopia, has never been detected elsewhere even in the same subspecies from the Neighboring countries. Moreover very recent morphometrical analyses described honeybee of Ethiopia as a single new subspecies, Apis mellifera simensis. In this paper, we aim to resolve this contradiction of classifying A.m.jeminitica. Using Dra I analyses and the partial sequence of the tRNAleu COII region of 30 sampled colonies along the river Nile in Sudan, we detected three different mtDNA lineage: A,O,and Y, each lineage compose of suit of haplotyps. We found the Y-lineage in 10% of the sampled colonies. This result report the existence of Y lineage in A. m. jemenitica of Sudan for the first time and gives further confirmation to the Y lineage in central and east Africa

On caligonellid mites (Acari: Trombidiformes: Prostigmata) of Iran

Mohammad Bagheri[1], Mansoureh Ahani Azad[2]

[1]University of Maragheh, Iran, [2]University of Maragheh, Iran

Mites of the family Caligonellidae are relatively small, reddish-colored, free-living predatory mites that feed on small arthropods. They often live on tree bark and in litter, soil, moss, storehouses and bird's nests. To date 11 species of this family bleonging to four genera, namely Neognathus Willmann, Molothrognathus Summers & Schlinger 1955, Caligonella Berlese 1910 and coptocheles Summers and Schlinger 1955, have been recorded from Iran. In a study of caligonellid mites of Northwest Iran, we collected 10 species of this family as bellow which two species are new species for caligonellid mites of world and marked by one asterik: Neoganthus terrestris (Summers & Schlinger, 1955) ; N. ueckermanni Bagheri, Do?an & Haddad, 2010; N. eupalopus Meyer & Ueckermann, 1989; N. spectabilis (Summers & Schlinger, 1955); Molothrognathus n. sp.1*; Molothrognathus n. sp.2 * ; M. bahariensis; M.azizi; M. mehrnejadi Liang & Zhang, 1997 and Caligonella humilis (Koch, 1838).

Mites of family Stigmaeidae (Acari: Trombidiformes) in Bonab orchards (Northwest Iran), with one new species of the genus *Stigmaeus* Koch, 1836

Saeede Sadat Gheblealivand[1], Mohammad Bagheri[2], Hamed Ghorbani[3]

[1]*University of Maragheh, Iran,* [2]*University of Maragheh, Iran,* [3]*Dryland Agricultural Researcher Instiute, Iran*

Stigmaeidae is the second most frequent and abundant group of predatory mites on plant leaves, after Phytoseiidae which feed on a variety of arthropods. They are small, red, yellow or orange mites that occur in many habitats and form an important component of the acarofauna of soil, litter and plants. In order to study of stigmaeid mites fauna of apple orchards of Bonab (East Azerbaijan province), sampling was taken during 2010 and the mites were extracted and cleared in Nessbit fluid and microscopic slides prepared. In this study, 6 genera and 13 species identified as fallows, of which one species is new and marked by two asterisks. Cheylostigmaeus gharekhanii Navaei-Bonab and Bagheri, 2011; Eustigmaeus nasrinae Khanjani & Ueckermann, 2002; E. segnis (Koch), Wood, 1973; E. setiferus Bagheri, 2011; E. azerbaijaneansis Haddad, 2011; Ledermuelleriopsis plumosa Willmann, 1951; L. zahiri Khanjani and Ueckermann, 2002; Stigmaeus boshroyehnsis Khanjani, 2010; S. elongatus Berlese, 1886; S. shabestariensis Haddad, Lotfollahi and Akbari, 2010; Stigmaeus sp.**, Storchia robustus (Berlese), Oudemans, 1923; Zetzellia mali (Ewing), Summers, 1960.

Morphological classification of Subfamily Dacinae (Diptera: Tephritidae) in China

Qinge Ji[1], Jiahua Chen[2], Nannan Zhang[3]

[1]Fujian Agriculture and Forestry University, China, [2]Fujian Agriculture and Forestry University, China, [3]Fujian Agriculture and Forestry University, China

Tephritidae (Insecta: Diptera) is one of the largest families which have economic significance. It includes 3 subfamilies i.e. Dacinae, Tephritinae and Trypetinae. More than 4500 species and 500 genera have been recorded in the world. Dacinae includes 3 tribes i.e. Ceratitidini, Gastrozonini and Dacini. Dacini includes 2 genera i.e. Bactrocera Macquart and Dacus Fabricius. Considerable concern has been expressed within Bactrocera Macquart for species complexes occurred. In this paper, more than 35000 specimens of Dacinae, collected from Henan (Luoyang), Jiangsu (Jintan, Nanjing), Chongqing, Jiangxi (Fuzhou), Fujian (Xiamen, Fuzhou, Zhangzhou, Gutian and Putian), Guangxi (Nanning, Guilin), Guangdong (Dongguan, Guangzhou), Guizhou (Guiyang), Yunnan (Jinghong, Yuanjiang and Jianshui), Hainnan (Wenchang, Danzhou and Sanya) in mainland China were identified. These specimens included 41 species described taxonomically and belonged to 2 tribes and 3 genera respectively, among them, 11 species and 2 records were new of China. The 11 new species were B. (B.) cheni, sp. nov., B. (B.) guiyangensis, sp. nov., B. (B.) hardyi, sp. nov., B. (B.) jinghongensis, sp. nov., B. (B.) nanningensis, sp. nov., B. (B.) nigrifacia, sp. nov., B. (Javadacus) ziai, sp. nov., B. (Z.) baoshanensis, sp. nov., B. (Z.) hendeli, sp. nov., B. (Z.) proprescutellata, sp. nov. and B. (Z.) zhaotongensis, sp. nov. Two new records were B. (B.) zonata (Saunders) and B. (Z.) vultus Hardy. 11 new species were described in English. Figures of 41 species and key to species were provided. All specimens are deposited in Fujian Agriculture and Forestry University.

On the *Anoplocheylus* Berlese, 1910 (Acari: Pseudocheylidae) mites of Iran, with description of two new species

Elham Zarei[1], Mohammad Bagheri[2], Mansoureh Ahaniazad[3]

[1]University of Maragheh, Iran, [2]University of Maragheh, Iran, [3]University of Maragheh, Iran

In order to study of Anoplocheylus Berlese,1910 species fauna of Iran, samples were taken from the soil of orchards and crop fields during 2010. By using the Berlese funnel, mites were extracted and microscopic slides prepared and then identified. In this study five species were identified of which two spices were new and indicated with asterisk as below. A key to all species of the genus Anoplocheylus is also provided. Pseudocheylidae: Anoplocheylus malayeriensis Ueckermann & Khanjani, 2004; Anoplocheylus tauricus Livshitz & Mitrofanov, 1970; Anoplocheylus bonabjadidiensis Navaei- Bonab, 2011; Anoplocheylus sp.1*; Anoplocheylus sp.2*

New detection of entomopathogenic fungi from the Sudan

Abdalla Abdelrahim Satti[1], Naiema Eltayeb Gorashi[2]

[1]Environment and Natural Resources Research Institute, Sudan, [2]Environment and Natural Resources Research Institute, Sudan

Entomopathogenic fungi are important biocontrol agents worldwide. Recent studies in Sudan have revealed numerous promising isolates. Fortuitously, an infected dead beetle showing dense fungal growths was encountered during 2010/11 on Lablab purpureus at El-Gurair, Northern Sudan. It is an unidentified pest of L. purpureus. Therefore, the sample was studied to identify the pathogenic agents. Part of fungal growths was cultured on PDA media and incubated in the dark at 240C. The variable growths obtained were purified, prepared on slides and studied for micro-morphological features. Based on literature, many fungi were identified (viz., Alternaria sp., Penicillium sp., Aspergillus sp., Paecilomyces sp. and Beauveria bassiana), but the latter two were stressed as important bioagents. The first one was characterized by white dense colony, slower growing, no zonation and white lower surface. Under (X100), dense clustered conidiogenous cells, flask shaped, with extended zigzag apexes, besides one celled hyaline globose conidia were seen. Moreover, a bioassay of this fungus against Epilachna elaterii has reflected the characteristic white muscardine sign. Such features suggested the detection of B. bassiana. However, the other fungus showed fast growing flat colony, powdery, initially white then turn brown all-round. Under (X40), well developed conidiophores bearing whorls of divergent branches ending with hyaline phialides were appeared. The conidia were ovoid, one-celled, with long dry chains. These features put this fungus under the genus Peacilomyces. So, the above two fungi were considered as first records in Sudan. They necessitate further studies to be evaluated in formulating biopesticides.

The physical therapy taxonomy

Ifedayo Augustine Falayi[1], Charles Chinonso Uduogu[2]

[1]New Era, Nigeria, [2]New Era, Nigeria

Background/Objective: Outcomes research is in need of a classification system of physical therapy (PT) interventions for acute traumatic spinal cord injury (SCI) rehabilitation in the United States. The objective of this study was to describe a taxonomy (system to categorize and classify interventions) to examine the effects of PT interventions on rehabilitation outcomes. Methods: The SCIRehab study uses the rigorous observational practice-based evidence methodology to examine current treatment processes without changing existing practice. PT clinicians and researchers from 6 centers developed a taxonomy to describe details of each PT session. Results: The PT taxonomy consists of 19 treatment activities (eg, bed mobility, transfers, wheelchair mobility, strengthening and stretching exercises) and supplementary information to describe the associated therapeutic interventions. Details that focus on patient assistance needs and family involvement are included as additional descriptors to help to describe and justify PT activity selection. Time spent on each activity is used as the measure of intensity. Conclusion: The detailed PT taxonomy documentation process, which offers efficiency in data collection, is being used for all PT sessions with 1,500 patients with acute traumatic SCI at the 6 participating centers. It might be the first attempt to document the many details of the PT rehabilitation process for patients with SCI in the United States.

An improved Greengenes taxonomy with explicit ranks for ecological and evolutionary analyses of bacteria and archaea

Ifedayo Augustine Falayi[1], charles chinonso Uduogu[2]

[1]New Era, Nigeria, [2]New Era, Nigeria

Reference phylogenies are crucial for providing a taxonomic framework for interpretation of marker gene and metagenomic surveys, which continue to reveal novel species at a remarkable rate. Greengenes is a dedicated full-length 16S rRNA gene database that provides users with a curated taxonomy based on de novo tree inference. We developed a 'taxonomy to tree' approach for transferring group names from an existing taxonomy to a tree topology, and used it to apply the Greengenes, National Center for Biotechnology Information (NCBI) and cyanoDB (Cyanobacteria only) taxonomies to a de novo tree comprising 408315 sequences. We also incorporated explicit rank information provided by the NCBI taxonomy to group names (by prefixing rank designations) for better user orientation and classification consistency. The resulting merged taxonomy improved the classification of 75% of the sequences by one or more ranks relative to the original NCBI taxonomy with the most pronounced improvements occurring in under-classified environmental sequences. We also assessed candidate phyla (divisions) currently defined by NCBI and present recommendations for consolidation of 34 redundantly named groups. All intermediate results from the pipeline, which includes tree inference, jackknifing and transfer of a donor taxonomy to a recipient tree (tax2tree) are available for download. The improved Greengenes taxonomy should provide important infrastructure for a wide range of megasequencing projects studying ecosystems on scales ranging from our own bodies (the Human Microbiome Project) to the entire planet (the Earth Microbiome Project). The implementation of the software can be obtained from

Faunal notes of family Arctiidae (Lepidoptera, Noctuoidea) from Korea

Ulziijargal Bayarsaikhan[1], Youngdon Ju[2], Mu-jie Qi[3], Xuan-Vi Le[4], Yang-Seop Bae[5]

[1]University of Incheon, Mongolla, [2]University of Incheon, Republic of Korea, [3]University of Incheon, [4]University of Incheon, Vietnam, [5]University of Incheon, Republic of Korea

The family Arctiidae belong to the superfamily Noctuoidea, with more than 11,155 named species, 750 genera all over the world (Heppner, 2005), small to large size, often quite robust and colorful, it was divided into three subfamilies: Lithosiinae, Arctiinae, and Syntominae (Kitching and Rawlins, 1999; Conner, 2009). The first Korean fauna of Arctiidae was published by Butler (1882), and he reported one species, Stigmatophora micans (Bremer et Gray). Arctiidae was mainly studied by a few foreign entomologists. After 1965, Korean entomologists began to research in this family. The taxonomic history of the Korean Arctiidae has recently revised by Park (2000), and he reported 75 species belonging to 31 genera including North Korea. Many checklists and references have been published about Arctiidae of Korea, we reviewed these references including our collection data. In this study, total of 63 species of 30 genera belonging to 2 subfamilies: Lithosiinae and Arctiinae in South Korea. Among them, one species is newly recorded, and one species has not been identified in genus Eilema from South Korea.

Biotaxonomy of the family Cicadidae from Vietnam(Hemiptera: Auchenorrhyncha)

Thai Hong Pham[1], Yong Jung Kwon[2]

[1]Institute of Ecology and Biological Resources, Vietnam, [2]Kyungpook National University, Republic of Korea

Vietnam is one of the world's hot spots of biodiversity, reflected in its great diversity of landscapes and ecosystems, partly depending on the long and diversely structured coastline and the wide range of latitudes and altitudes of the country. Cicadas are ecologically important because they are the major root-feeding herbivores in tropical forests and also serve as a food source for birds and other insectivorous vertebrates (including humans!). Because of their multi-year life-cycles and dependence on mature, intact forest habitats, they have also proven to be very valuable as indicators of forest habitat integrity. Faunal studies on cicadas in this region would also contribute to our understanding of general mechanisms that have generated high biodiversity in the region. All three subfamilies of Cicadidae, the Cicadinae, Cicadettinae, and Tettigadinae, are now known to be represented in Vietnam. A total of 132 species and 47 genera of Cicadidae from Vietnam were taxonomically revised. There are 16 species, 7 genera, and 4 tribes of Cicadettinae, 115 species, 39 genera, and 7 tribes of Cicadinae, and 1 species of Tettigadinae respectively. The relative percentage of the species richiness in Cicadinae (87.12%), Cicadettinae (12.22%) and Tettigadinae (0.76%) respectively conducted based on the revision work. Presented here, we have identified one genus new to science, which belong to subfamily Cicadinae. Eight species: Platypleura mira Distant, 1904, Oxypleura calypso Kirby, 1888, Gaeana laosensis Distant, 1917, Gaeana vestita Distant, 1905, Haphsa fratercula Distant, 1917, Haphsa opercularis Distant, 1917, Macrosemia divergens (Distant, 1917), Macrosemia assamensis (Distant, 1905) are considered

Different physiological roles of two dopamine receptors in isolated salivary glands of the blacklegged tick, *Ixodes scapularis*.

Donghun Kim[1], Ladislav Simo[2], Yoonseong Park[3]

[1]Kansas State University, U.S.A., [2]Kansas State University, U.S.A., [3]Kansas State University, U.S.A.

Ticks are obligatory ectoparasites of many vertebrate transmitting pathogens causing diseases including the Lyme disease. Tick salivary secretion is crucial not only for successful feedings for injection of bioactive salivary components into the host but also for osmoregulation after the ingestion of large amount of blood. Control of the salivary glands involves dopamine that is the most potent salivation inducer. We previously have identified two dopamine receptors expressed in the salivary glands and named as dopamine receptor (D1) and dopamine-like receptor (D1L) based on their sequence similarities to the vertebrate dopamine receptors. We established heterologous functional assays of each receptor for pharmacological characterizations. We have identified one D1 specific agonist (SKF82958) and two D1L specific antagonists (acepromazine and fluphenazine) that pharmacologically discriminate the two receptors. Isolated tick salivary glands were examined for measuring the secretory activities after pharmacological treatments. Increases in the volume of individual acinus of the salivary glands were measured over time after the treatment. Based on the results from our studies using receptor-specific antagonists and agonists, dopamine triggers two different physiological actions through two respective receptors. We propose that high-sensitive receptor D1 triggers fluid transport in the epithelial cells of the acini and low-sensitive receptor D1L is involved in pumping actions of the acini. Understanding the mechanisms of tick salivary gland control will allow us to develop the novel method for disruption of tick feeding.

Cuticular lipids, water loss and desiccation resistance changes in *Z. indianus* and *D. melanogaster*

Bhawna Kalra[1], Ravi Parkash[2]

[1]*M.D.University, India,* [2]*M.D.University, India*

We investigated within as well as between population variability in desiccation resistance, cuticular lipid mass per fly and cuticular water loss in nine geographical populations of a tropical drosophilid, Zaprionus indianus. Interestingly, the amount of cuticular lipids and desiccation resistance in this non-melanic species are significantly higher as compared with melanic Drosophila melanogaster. On the basis of isofemale line analysis, within population trait variability in cuticular lipid mass per fly is positively correlated with desiccation resistance and negatively correlated with cuticular water loss but show lack of correlation with body size. We observed geographical variation in the amount of cuticular lipid mass per fly in Zaprionus indianus but no such divergence was found in D. melanogaster. In both the species, geographical variations in desiccation resistance are negatively correlated with cuticular water loss but the underlying mechanisms for changes in cuticular permeability are quite different. Thus, we may suggest that body melanisation and cuticular lipids may represent alternative strategies for coping with dehydration stress in melanic versus non-melanic drosophilids. For both the species, desiccation resistance and cuticular water loss are correlated with regular increase in aridity in the northern subtropical localities as compared with southern peninsular humid tropical localities.

Molecular characterization of the cDNA encoding chitinase and its expression in oriental fruit fly Bactrocera dorsalis

Wen-Jia Yang[1], Kang-Kang Xu[2], Wei Dou[3], Jin-Jun Wang[4]

[1]Southwest University, China, [2]Southwest University, China, [3]Southwest University, China, [4]Southwest University, China

Insect chitinases belong to a large and diverse family of hydrolytic enzymes, which are responsible for chitin degradation in the cuticle and peritrophic matrix (PM) during the insect molting. In this study, we have identified a cDNA putatively encoding a chitinase and named it as BdCht2 (GenBank accession number: JN100105) in the oriental fruit fly Batrocera dorsalis. The BdCht2 gene consists of four exons and three introns and encodes peptide of 483 amino acid residues, which was composed of a singal peptide, a chitin active site, a linker region and a chitin-binding domain. Phylogenetic analysis suggested that BdCht2 is orthologous to the Cht2 proteins identified in other insect species. Real-time quantitative PCR showed that BdCht2 was expressed at all tested developmental stages, and expressed at highest level in the third larva stage. Furthermore, the BdCht2 transcript was predominately found in larva midgut. The results support the hypothesis that BdCht2 is responsible for digesting the chitin associated with the PM in epithelial cells of the midgut. Further studies will be necessary to elucidate the biological functions of BdCht2 gene in the oriental fruit fly. By using a feeding- based RNAi technique, we will detect the BdCht2 transcript level of the larva midgut and chitin content in the PM as compared with the control larvae fed on the diet containing GFP dsRNA. The results about the effect of BdCht2 knock down on midgut chitin metabolism can provide evidence that BdCht2 whether affects the growth and developmental of the larvae B. dorsalis.

Molecular mechanisms of acaricides resistance in *Panonychus citri* (Acari: Tetranychidae)

Tian-Bo Ding[1], Kun Zhang[2], Wei Dou[3], Jin-Jun Wang[4]

[1]Southwest University, China, [2]Southwest University, China, [3]Southwest University, China, [4]Southwest University, China

The citrus mite, Panonychus citri (McGregor) is the most common and important spider mite pest of citrus orchards in China. Chemical spraying and several biological/ecological traits of P.citri that make it develop resistance rapidly to acaricides. As a result, P. citri become the third species that develop severe resistance from the family Tetranychidae. Our results showed that the significant correlation between GSTs activity and the LC50 of pyridaben existed, suggested that GSTs could be associated with varying susceptibility levels to pyridaben. After selection with abamectin and fenpropathrin in the laboratory, activities of detoxification enzyme, CarE was related to these two acaricides resistance. After induced by four different acaricides (abamectin, azocyclotin, pyridaben and spirodiclofen), the expression levels of two P450 genes, cyp4cf1 and cyp4cl2, both increased. In addition, six GSTs genes and 11 CES genes were cloned and the expression profiles were analyzed. An unprecedented 4 gigabase pairs cDNA library including four developmental stages of P. citri (eggs, larval, nymphal, adult) was constructed by using the cost-effective short read sequencing technology (Illumina). A total of 132 unigenes (composed by 79 of P450s, 24 of GSTs, 13 of CES, 1 of AChE, 1 of VGSC, 10 of nAChR, 3 of GABA receptor and 1 of Cytb) which could be associated with acaricides resistance were identified.

A quantitative assay for juvenile hormones and their precursors using fluorescent tags

Crisalejandra Rivera-Perez[1], Marcela Nouzova[2], Fernando Gabriel Noriega[3]

[1]Florida International University, U.S.A., [2]Florida International University, U.S.A., [3]Florida International University Miami, FL, U.S.A.

The lipophilic character of JH, its low concentration, fragility and the tendency to bind nonspecifically to everything had made difficult its quantification. A sensitive and robust new method was developed to quantify JH and its precursor pools in biological samples. The assay is based on the derivatization of JH with fluorescent tags, with subsequent analysis by reverse phase HPLC and a fluorescent detector (HPLC-FD). Linear responses were obtained over the range of 10-20 to 1000 fmols. Opening of the epoxide ring converts JH III into a diol form that is more hydrophilic and less adsorbed onto surfaces (less "sticky"). We successfully tagged the carboxyl groups of 5 precursors hydroxymethylglutaryl-CoA, mevalonate, mevalonate phosphate, mevalonate diphosphate and farnesoic acid (FA); the thiol groups of acetyl-CoA and acetoacetyl-CoA, the hydroxyl group of farnesol and the aldehyde group of farnesal. All these compounds were detected in mosquito corpora allata-corpora cardiaca extracts (CA-CC). FA and JH III levels were reproducibly quantified from CA-CC, hemolymph and whole body of female adult mosquito (in addition, JH III and JH III bisepoxide were detected in whole body of adult Drosophila melanogaster). The HPLC-FD protocol is simple, fast and relatively inexpensive; when quantifying JH from hemolymph or CA samples, the total time needed to extract the sample, open the ring and derivatize the sesquiterpene was less than 90 min and multiples samples can we processed simultaneously. Quantification from whole body samples is more laborious and takes around 6h.

Effects of thyroxin and potassium iodid on biological and physiological paramerters of the mulberry silkworm, *Bombyx mori* L (Bombycidae: Lepidoptera)

Gadelhak Gaber Gadelhak[1], Ibrahim A. Rawash[2], Abir A. Gad[3], Mamdouh H. Idress[4]

[1]Alexandria University, Egypt, [2]Alexandria University, Egypt, [3]Alexandria University, Egypt, [4]Alexandria University, Egypt

Thyroxin and potassium iodid have been used as suplementary nutrients for the mulburry silkworm, Bombyx mori L. Ascending concentrations were applied to mulberry leaves as a source of food at the last larval instar. Treatments with potassium iodide at concentrations ranged from 10 to 75 ?g/ml significantly increased the mean weight of mature larvae, pupae, cocoon shells as well as silk glands. The cocoon shells weight and mean number of deposited eggs/female increased by about 31.7 and 32.8%, respectively, when larvae were fed on mulberry leaves treated with 50 ?g/ml potassium iodide. Results indicated that all tested concentrations of thyroxin (10 to 50 ng/ml) significantly increased the mean weight of mature larvae, pupae and cocoon shells. The use of thyroxin at the concentrations 100 ng/ml increased silk and eggs production by about 33.9 and 23.99%, respectively. The tested compounds had a positive effect on the silkworm CA activity and the total haemolymph proteins.

Effects of insulin as a peptide hormone and estradiol as a steroid one on physiological and biological parameters of the silkworm, Bombyx mori L (Bomycidae: Lepidoptera)

Gadelhak Gaber Gadelhak[1], Ibrahim A. Rawash[2], Abir A. Gad[3], Mamdouh H. Idriss[4]

[1]Alexandria University, Egypt, [2]Alexandria University, Egypt, [3]Alexandria University, Egypt, [4]Alexandria University, Egypt

Effects of Insulin on B. mori larvae was studied on the last larval instar that was injected with doses ,0.01, 0.05, 0.1 and 0.4 IU/larva. Doses increased the mean weights of mature larva, pupa, silk gland, cocoon shell and number of deposited eggs/female. The moderate dose of Insulin, 0.05 IU/larva increased the mean weights of larva, pupa, silk gland, cocoon shell by about 27.3%, 29.7, 23.2 % and 19.08 % respectively. Also, the same dose caused an increase in the number of deposited eggs/female by about 42.6 %. Moreover, the treatment with 0.05 IU/larva caused an increase in the total hemolymph proteins by about 37.5%. The same dose of insulin increased the CA surface area by about 36.7% more than control. The effect of estradiol on the last larval instar of B. mori at concentrations of 50, 100, 250 and 500 ?g/L was studied. The mean weights of mature larva, pupa, silk gland and cocoon shell have been significantly increased. Estradiol at the rate of 100 ?g/L increased the mean weights of larva, pupa, silk gland by about 45.5%, 20.2%, 55.3% and 29.8% respectively. The same concentration caused an increase in the number of deposited eggs per female. It als, increased the total hemolymph proteins. Moreover, the treatment with estradiol caused an increase in the CA surface area by about 43.5% more than control

Are microsatellite mutation rates higher in Orthopterans?

Marie-Pierre Chapuis[1], Christophe Plantamp[2], Rejane Streiff[3], Laurence Blondin[4], Gregory Sword[5]

[1]CIRAD, France, [2]CIRAD, France, [3]INRA, France, [4]CIRAD, France, [5]Texas A&M University, France

Much remains to be learned about the mutational processes governing the evolution of microsatellite repeat regions. Empirical data on microsatellite mutation rates in insect taxa is notably lacking. Here we first analyzed microsatellite within-population diversity compiled from the literature. This survey of 210 insect species from six major orders revealed that within Orthopterans levels of genetic diversity were ~20% higher and microsatellite repeat arrays were longer than in any other group. Because of the mutation dependence on repeat length, this result suggests a higher microsatellite loci mutation rate in the Orthoptera. We then tested empirically this hypothesis in the Desert locust, Schistocerca gregaria, by estimating germline mutation rates at 10 microsatellite loci from pedigree data.

Phylogeography of the walnut twig beetle, *Pityophthorus juglandis* Blackman, the insect vector of Thousand Cankers Disease, in the United States

Paul Rugman-Jones[1], Richard Stouthamer[2], Andrew D. Graves[3], Steven J. Seybold[4]

[1]University of California Riverside, U.S.A., [2]University of California Riverside, U.S.A., [3]USDA - Forest Service, Albuquerque, NM, U.S.A., [4]USDA - Forest Service, Davis, CA, U.S.A.

Over the past decade, widespread dieback of walnuts (Juglans spp.) in the western United States, has been attributed to Thousand Cankers Disease (TCD). TCD results from aggressive feeding in the phloem by the walnut twig beetle (WTB), Pityophthorus juglandis, accompanied by inoculation of its feeding galleries with a pathogenic fungus, Geosmithia morbida carried on the surface of the beetle, instigating canker development in the phloem. Symptomatic trees typically die within 3 years. WTB has a long collection history in the southwestern U.S. and northern Mexico (collected in 1896, New Mexico; 1907, Arizona; 1959, California; 1960, Mexico). However, WTB has not historically been considered a major pest of walnut trees and TCD appears to be a new phenomenon. Since the early 1990's, the distribution of WTB has expanded, accompanied by the threat of TCD. WTB is now known from the western U.S. states of California, Oregon, Washington, Nevada, Utah, Arizona, New Mexico, Colorado, and Idaho. More significantly, WTB (and TCD) has now been detected in the eastern U.S. states of Tennessee (2010), Virginia (2011), and Pennsylvania (2011), placing the disease in direct proximity to highly valuable (> $500 billion) native timber stands of eastern black walnut, Juglans nigra. Using mitochondrial DNA we examined variation among over 60 U.S. populations of WTB and found evidence of two clearly divergent lineages. Little geographic overlap of these lineages occurs, but parapatric populations exist in Colorado, New Mexico, and Utah. The specific status of WTB, and potential phylogeographic and evolutionary origins of TCD are discussed.

Transcriptomic analysis of oocyte resorption after hydric stress in the German cockroach

Maria Dolors Piulachs[1], Anibal de Horna[2], Alba Herraiz[3], Xavier Belles[4]

[1]Institute of Evolutionary Biology (CSIC-UPF), Spain, [2]Institute of Evolutionary Biology (CSIC-UPF), Spain, [3]Institute of Evolutionary Biology (CSIC-UPF), Spain, [4]Institute of Evolutionary Biology (CSIC-UPF), Spain

Water stress impairs reproduction on insects, causing oocyte resorption in females. The present communication describes the molecular changes underlying oocyte resorption that occur in the German cockroach, Blattella germanica, after water deprivation. We suppressed drinking water to B. germanica females on day three of the adult life, and fluorescence microscopy showed that ovarian resorption started between 1 and 2 days later, as evidenced by a severe disorganization of the cytoskeleton. To identify genes that might be involved in oocyte resorption we carried out RNA ultrasequencing and obtained two respective transcriptomes from ovaries of five-day-old females: one from control specimens and the other from females that were water-deprived two days earlier. The comparative analysis of these two transcriptomes revealed that sequences that are differential expressed, with a p-value of 0.999, are mostly assigned to a Gene Ontology terms related with structural cell components. Transcripts related with processes of proteolysis and engulfment are up-regulated, whereas those involve in cell components organization are down-regulated in the ovaries from water-deprived females, which highlight the state of cellular disintegration involved in resorption. Further steps of this study would be to select the most significant transcripts, to validate the quantitative changes by qRT-PCR, and to carry out RNAi studies to assess their functions.

Kruppel homolog 1 and metamorphosis in the German cockroach. Expression, post-transcriptional regulation by microRNAs and biological role

Jesus Lozano[1], Raul Montanez[2], Xavier Belles[3]

[1]Institute of Evolutionary Biology (CSIC-UPF), Spain, [2]Institute of Evolutionary Biology (CSIC-UPF), Spain, [3]Institute of Evolutionary Biology (CSIC-UPF), Spain

Endocrinologically speaking, metamorphosis is regulated by ecdysteroids, which induce molts, and juvenile hormone (JH), which repress metamorphic changes. At a molecular level, the action of ecdysteroids has been thoroughly studied in two species, in the highly derived fly Drosophila melanogaster, which is a holometabolous model, and in the less-derived cockroach Blattella germanica, a hemimetabolous species. Conversely, the molecular action of JH is poorly understood, with the bulk of data being available for holometabolous models. Research on the molecular action of JH in hemimetabolous species is therefore needed in order to elucidate the evolution of insect metamorphosis from hemimetaboly to holometaboly. In light of this, we have studied the function of Kruppel homolog 1 (Kr-h1) in B. germanica. Kr-h1 is a Zn finger transcription factor whose function as transductor of the antimetamorphic action of JH has recently been demonstrated in D. melanogaster and in the beetle Tribolium castaneum. The expression studies during the last nymphal instars show that Kr-h1 is suddenly down-regulated 24 h after the molt to the last instar nymph, and anti-miR experiments suggest that miR-2/miR-13 family of microRNAs might be involved in such a regulation. Importantly, RNAi experiments indicate that Kr-h1 has a repressor role in the frame of the JH signalling pathway and in the context of metamorphosis, as occurs in D. melanogaster and T. castaneum, thereby suggesting that this role has been conserved from cockroaches to flies, i.e., across some 350 million years of insect evolution.

The microRNA let-7 has a key role in insect vein patterning during wing metamorphosis

Mercedes Rubio[1], Xavier Belles[2]

[1]Institute of Evolutionary Biology (CSIC-UPF), Spain, [2]Institute of Evolutionary Biology (CSIC-UPF), Spain

In most insects, the miRNA let-7 clusters with miR-100 and miR-125 in the same primary transcript. The three miRNAs are involved in developmental timing in the nematode Caenorhabditis elegans and in the fly Drosophila melanogaster. In the cockroach Blattella germanica, the expression of these miRNAs peaks in the last instar nymph, before metamorphosis. When let-7 and miR-100 are depleted with specific anti-miRNAs, the resulting adult shows the wings malformed: either reduced in size (anti-miR-100) or with wrong vein patterning (anti-let-7). Depletion of miR-125 induces no apparent effects. In D. melanogaster, many are genes involved in wing maturation, and one of them is the Drosophila serum response factor (DSRF). Towards the end of the last instar larvae, previous to metamorphosis, DSRF expression is down-regulated in the longitudinal veins by Ras-mediated epidermal growth factor (Egfr) signaling. Reduction of DSRF expression seems necessary to reach a right proportion between wing veins and interveins. In B. germanica wing buds, DSRF is down-regulated during the last instar nymph, in parallel to the up-regulation experienced by let-7. We propose that let-7 plays a key role in vein-intervein patterning of B. germanica by targeting DSRF mRNA, thus helping to down-regulate the expression of this gene post-transcriptionally.

Progress of subunit composition studies on nicotinic acetylcholine receptors from *Nilaparvata lugens*, an important rice insect pest

Jian Li[1], zewen Liu[2]

[1]*Nanjing Agricultural University, China,* [2]*Nanjing Agricultural University, China*

The subunit composition of insect nicotinic acetylcholine receptors (nAChRs) decided the pharmacology properties of the receptors, such as the effects of point mutations on insecticide resistance. We obtained evidences for the co-assembly of two Nilaparvata lugens nAChR α subunits (Nlα1 andNlα2) with rat β2 subunit into a receptor complex, a functional triplet nAChR (Nlα1/Nlα2/β2), in Xenopus oocytes. We also demonstrated that N. lugens Nlα3 and Nla8 and with rat β2 subunit into another triplet nAChR (Nlα3/Nlα8/β2). Nlα3/Nlα8/β2 was more sensitive to imidacloprid than Nlα1/Nlα2/β2, and the previous identified mutation Y151S in Nlα3 showed more effects on the imidacloprid sensitivity in Nlα3/Nlα8/β2 than Y151S mutation in Nlα1 of Nlα1/Nlα2/β2, which indicated that Y151S mutation in Nlα3 might be more important in contributing to neonicotinoid resistance than the Nla1 Y151S mutation in N. lugens. Previous study revealed that two binding sites for imidacloprid with different affinities in N. lugens. Co-immunoprecipitation studies with native preparations of N.lugens nAChRs demonstrated the co-assembly of three insect subunits (Nlα1, Nlα2 and Nlβ1) into one receptor complex and of Nlα3, Nlα8 and Nlβ1 into another. In native preparations of N. lugens nAChRs, the deletion of [3H]imidacloprid binding by subunit-selective antisera immunoprecipitation indicated that Nlα1, Nlα2 and Nlβ1 (Nlα1/Nlα2/Nlβ1) contributed to a low affinity binding site (Kd=1.5±0.2 nM) for imidacloprid and Nlα3, Nlα8 and Nlβ1 (Nlα3/Nlα8/Nlβ1) contributed to a high affinity binding site (Kd=3.5±0.6 pM).

Molecular characterization and functional study on chitin synthase genes from *Locusta migratoria*

Xiaojian Liu[1], Kun Yan Zhu[2], Yaping Guo[3], Enbo Ma[4], Jianzhen Zhang[5]

[1]Shanxi University, China, [2]Kansas State University, U.S.A., [3]Shanxi University, China, [4]Shanxi University, China, [5]Shanxi University, China

Current knowledge on chitin synthase (CHS), especially their structures, functions, and regulations in insects is still very limited. We characterized two chitin synthase genes, LmCHS1 and LmCHS2, from Locusta migratoria. LmCHS1 and LmCHS2 were predicted to encode proteins of 1,576 and 1,523 amino acid residues, respectively. Their deduced amino acid sequences show high similarities to other insect chitin synthases. Furthermore, two alternatively spliced transcripts of LmCHS1, LmCHS1A and LmCHS1B, were identified. The two variants differ only in one exon consisting of 177 nucleotides. Analysis of expression levels of these transcripts in different tissues and developmental stages indicated that LmCHS1A predominates in the integument during all developmental stages, whereas LmCHS1B is more abundantly present in the tracheae and LmCHS2 was specifically expressed in midgut and gastric caeca during feeding stages. Functional analysis of the two chitin synthase genes revealed unique and complementary roles. The phenotypes resulted from injection of LmCHS1A dsRNA were similar to those from the injection of LmCHS1 dsRNA, insects can not detach old cuticle and molt to the next stadium, whereas the locusts injected with LmCHS1B dsRNA exhibited crimpled cuticle phenotype. However, LmCHS2-specific RNAi had no effect on morphology of locusts, but the average length of midgut is shorter than those from control insects and the formation of well structured peritrophic matrix was disrupted in HE stained LmCHS2 dsRNA-treatment samples. Our results suggest that both chitin synthase genes are essential for insect growth and development and may represent an attractive target site for controlling locusts.

Identification and functional characterization of sex pheromone receptors in two sibling species, *Helicoverpa armigera* and *Helicoverpa assulta*

Xiao-Jing Jiang[1], Dan-Dan Zhang[2], Ling-Qiao Huang[3], Chen-Zhu Wang[4]

[1]Chinese Academy of Sceinces, China, [2]Chinese Academy of Sceinces, China, [3]Chinese Academy of Sceinces, China, [4]Chinese Academy of Sceinces, China

Sex pheromones released by female moths are detected with high specificity and sensitivity in the olfactory sensilla of antennae of conspecific males. The two sibling species, Helicoverpa armigera and Helicoverpa assulta, are important agricultural pests around the world. They share the same two main sex pheromone components, Z11-16: Ald and Z9-16: Ald, but with almost reversed ratio. Here we identify the four sex pheromone receptors from the two Helicoverpa species. Functional analyses of the sex pheromone receptors are conducted using heterologous expression in Xenopus laevis oocytes and two-electrode voltage clamp recordings. Meanwhile, we compare expression levels of these genes between the male and female antennae in the two species.

Molecular physiology of epithelial water transport in the lepidopteran hindgut

Masaaki Azuma[1], Tomone Nagae[2], Mariya Maruyama[3]

[1]Tottori University, Japan, [2]Tottori University, Japan, [3]Tottori University, Japan

Aquaporin (AQP), water channel, facilitates first and foremost the transmembrane transport of water molecules and is now recognized as one of the key players in epithelial and cellular osmoregulaton in insects. In the silkworm, Bombyx mori, the movement of water through the epithelia within the cryptonephric rectal complex is likely facilitated by the two AQPs, AQP-Bom1 and AQP-Bom3. Both are functionally water-specific. Phylogenetically, AQP-Bom1 and AQP-Bom3 belong to the DRIP (Drosophila integral protein) and PRIP (Pyrocoelia rufa integral protein) subfamilies, respectively, of the insect AQP clade. AQP-Bom1 [DRIP] was exclusively expressed at the apical plasma membrane of colonic and rectal epithelial cells, whereas AQP-Bom3 [PRIP] was expressed at the basal plasma membrane of these cells. This polarised localisation of DRIP/PRIP was also observed in the outer cryptonephric Malpighian tubules (outer cMT) and in the six tubules just outside the cryptonephric rectal complex (rectal lead MT). In the rectal complex, water is transported from the rectal lumen to the perinephric space and then deposited into the lumen of the outer cMT; the water then goes through the tubular lumen to exit the complex and is finally transported across the rectal lead MT, which is the very limited region of the water-permeable sites in MT epithelia. Two distinct water-specific AQPs as "DRIP: apical ~ PRIP: basal orientations" confer high-capacity water flow with a transcellular manner and function in retrieving water in the epithelial cells of lepidopteran hindgut. This process circumvents unnecessary water loss and protects caterpillars from accidental starvation.

Structure activity relationship of a novel juvenile hormone, JHSB3

Tetsuro Shinada[1], Kanako Kaihara[2], Toyomi Kotaki[3], Hideharu Numata[4], Yasufumi Ohfune[5]

[1]Osaka City University, Japan, [2]Osaka City University, Japan, [3]National Institute of Agrobiological Sciences, Japan, [4]Kyoto University, Japan, [5]Osaka City University, Japan

The juvenile hormone (JH) has been expected to be a prime lead molecule for developing a "third-generation pesticide", because of its significant growth regulation effects in insects. Heteroptera includes many agricultural and medical pests. The development of Heteroptera-specific insecticides poses a pivotal subject in this field. We have reported the structure determination of a novel juvenile hormone, JHSB3, isolated from a stink bug, Plautia stali (Kotaki, et al., Org. Lett. 2009, Kotaki, et al, Psyche, 2012, review). In this paper, we would like to describe the structure activity relationship of JHSB3 toward development of Heteroptera-specific insecticides. JHSB3 [methyl (2R,3S,10R)-2,3;10,11-bisepoxyfarnesoate] bears two epoxides, and olefin and methyl ester moieties, on the sesquiterpene skeleton. The JH analogs in which the functional groups of JHSB3 were removed or substituted with other functional groups have been prepared. These analogs were subjected to juvenilizing activity tests using P. stali. The results indicated that the co-existence of the ester carbonyl group and two epoxides was proved to be crucial for the potent juvenilizing activity. Among the tested compounds, we found highly potent analogs in which the olefinic double bond of JHSB3 was saturated. The methoxy analogs in which the 10,11-epoxide moiety was substituted with a methoxy group exerted a moderate juvenilizing activity (Kaihara, , et al., Tetrahedron, 2012).

Analysis of expression pattern of *Bombyx mori* gustatory receptors in the tissues and single cells of the taste organs.

Kazuya Shimomura[1], Ryoichi Sato[2]

[1]Tokyo University of Agriculture & technology, Japan, [2]Tokyo University of Agriculture & technology, Japan

Insects distinguish host plants and others making full use of gustatory sense. Therefore, understanding gustatory system of insects is expected to reveal selection mechanism of host, leading to contribution to insect pest control. Taste substances are recognized by insects using gustatory neurons that express 7-transmembrane receptors assigned to insect gustatory receptor (Gr) family. Many groups have been trying to identify ligands of the Grs using heterologous expression system, but few good results were obtained. One possible reason is that Grs do not function as monomeric receptors, but heterogeneous multimers in combination with other members of the Gr family. Therefore, to identify the ligands of the Grs and to understand gustatory system of insects, it is very important to reveal expression pattern of Grs in each gustatory neurons. We tried to investigate expression pattern of Grs in various tissues and single cells of Bombyx mori larvae which eats selectively mulberry leaves. First, RT-PCR analysis of BmGr expression in antennae, labrum, maxillary lob, maxillary palpus and midgut from larvae was performed. Next, expression pattern of Grs in single gustatory neurons innervating sensilla of the gustatory organs were attempted to investigate by RT-PCR in combination with Laser capture microdissection (LCM). Frozen section of the gustatory organs of B. mori which was previously injected with methylene bule were prepared and stained cells were isolated from the section by LCM. Subsequently, BmGrs being present in the collected cells were examined by RT-PCR. In this conference, we will present the results of these experiments.

The role of the TOR pathway in the regulation of juvenile hormone synthesis in *Aedes aegypti*.

Mertixell Perez-Hedo[1], Crisalejandra Rivera-Perez[2], Marcela Nouzova[3], Fernando Gabriel Noriega[4]

[1]*Florida International University, U.S.A.,* [2]*Florida International University, U.S.A.,* [3]*Florida International University, U.S.A.,* [4]*Florida International University, U.S.A.*

Juvenile hormone III (JH III) plays a central role in regulating ovarian development in female Aedes aegypti mosquitoes. The activation of JH synthesis and the previtellogenic development of the ovaries are stimulated only when nutrients are adequate. The protein kinase TOR (Target of Rapamycin) is the central node of a highly conserved signaling network that regulates cell growth in response to nutrients, hormones and stress. We are using several experimental approaches to test the role of the TOR signaling pathway on the transduction of nutritional signals in the mosquito CA. 1) To study the effect of rapamycin (an inhibitor of TOR) and nutrients on phosphorylation of two major downstream targets of TOR: p70S6 kinase and 4E-binding protein in the mosquito CA 2) To evaluate the effect of rapamycin on the levels of JH synthesis and its precursors using high performance liquid chromatography and fluorescent detection (HPLC-FD), 3) To evaluate the effect of RNAi depletion of specific components of the TOR pathway on JH synthesis, and 4) To evaluate the effect of manipulating the TOR signaling on the mRNA levels of the JH biosynthetic enzymes. We aim to demonstrate that the TOR signaling pathway is involved in the nutritional regulation of CA activity in mosquitoes, and reveal how nutritional signal pathways crosstalk to other regulators (such as allatoregulatory peptides) to modulate JH synthesis.

The photoresponse of the brown-winged green stinkbug, *Plautia stali*: The daily activity rhythm and phototaxis.

Masami Shimoda[1], Terumi Yamaguchi[2], Takuya Uehara[3], Toyomi Kotaki[4]

[1]National Institute of Agrobiological Sciences, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]University of Tsukuba, Japan, [4]National Institute of Agrobiological Sciences, Japan

The brown-winged green stinkbug, Plautia stali, is an important pest of fruit trees in East Asia, including Japan. However, little is known of its daily activity rhythm and phototactic behavior. This study investigated the daily distribution of locomotor activity in its natural environment and the wavelength dependence of its phototactic behavior at night. Insects were collected in an orchard in Tsukuba and progeny until the fifth generation were used for the experiments. The adults were reared individually in plastic dishes and the locomotor activity was recorded continuously for 1 week in a cypress grove. Under natural light, P. stali had morning and evening activity peaks. The greatest activity was in the 3~4 hours after sunset (dusk to midnight). We also performed a trajectory analysis of the phototactic behavior (attraction to a monochromatic light-emitting diode (LED)) in a wide open-field arena. Phototactic behavior was evoked toward dim light (1×10^15 photons/m2/s) and the animals were attracted to a wide range of wavelengths (from ultraviolet (UV) to red). The most attractive wavelengths were 365 nm (UV) and 525 nm (green). We discuss the adaptive importance of the photoresponse behavior of P. stali.

Mode of binding of juvenile hormone binding protein with ligands

Takahiro Shiotsuki[1], Rintaro Suzuki[2], Zui Fujimoto[3], Wataru Tsuchiya[4], Mitsuru Momma[5], Akira Tase[6], Mitsuhiro Miyazawa[7], Toshimasa Yamazaki[8]

[1]National Institute of Agrobiological Science, Japan, [2]National Institute of Agrobiological Science, Japan, [3]National Institute of Agrobiological Science, Japan, [4]National Institute of Agrobiological Science, Japan, [5]National Institute of Agrobiological Science, Japan, [6]National Institute of Agrobiological Science, Japan, [7]National Institute of Agrobiological Science, Japan, [8]National Institute of Agrobiological Science, Japan

Juvenile hormones (JHs) are involved in many aspects of physiology in development and reproduction. The regulation of JH titer is crucial to normal development in insects. JH titer is mainly regulated by the control of its synthesis and degradation. Also, hemolymph JH binding protein (JHBP) is known for its importance to transfer JH to peripheral tissues in Lepidoptera. The structural mechanism of JH delivery by JHBP was analyzed based upon the crystal and solution structures of apo- and JH-bound JHBP of silkworm. JHBP has two hydrophobic pockets at both ends of the molecular structure, and only one of those is found for JH-binding. JH-binding to the gate-open form results in the fully closed JHBP-JH complex structure where JH is buried completely inside the protein. At the binding site, JH is stabilized by several hydrogen bonds to set an L-shaped form surrounded with several aromatic amino acid residues. JHBP in complex with JH opens the gate helix to release the bound hormone likely by sensing reduction of the dielectric constant at the membrane surface of the target organs. The results obtained reveal the structural mechanism for JH delivery by JHBP in hemolymph, the first essential process of the JH signal transfer.

Embryonic development of a diving beetle, *Hydaticus pacificus* (Coleoptera, Dytiscidae)

Kazuhiro Niikura[1], Yukimasa Kobayashi[2], Kei Hirasawa[3], Toshio Inoda[4]

[1]Tokyo Metropolitan University, Japan, [2]Tokyo Metropolitan University, Japan, [3]Aquamarine Fukushima, Japan, [4]Shibamata 5-17-10, Katsushika, Tokyo, Japan

The successive changes of developing embryos of Hydaticus pacificus were described from observations based on light and electron microscopy. The eggs of this species were deposited on water grasses by breeding females in a laboratory. The egg period was about 50 hours under the condition of 28 degree centigrade. The newly laid egg is nearly cylindrical, and is about 2.20 mm long and 0.68 mm wide. As development proceeds, the egg becomes 2.70 mm long and 0.85 mm wide in maximum. The chorion is smooth and thin, and almost transparent throughout the whole egg surface. The early germ band, or embryo, is long, occupying about four fifths of the egg length, and is formed on the ventral surface of the egg. The embryo then elongates and widens, retaining this superficial position throughout development. The openings of the tracheal invaginations, or spiracles, appear in the body wall of the mesothoracic, metathoracic, and the first eight abdominal segments. The spiracles except for those of the eighth abdominal segment, however, close and disappear at late embryonic stages, and the spiracles in the eighth segment remain as those of the newly hatched larva. At the abdominal end the ninth and 10th abdominal segments fuse, and thus the abdominal region consists of nine segments, although the ninth or last segment is highly reduced. Urogomphi appear as a pair of slender projections at the abdominal end. Pleuropodia are formed in the first abdominal segment, but no appendage-like projections appear in other abdominal segments.

Accumulation of antidiabetic iminosugars in silkworms reared on mulberry leaves

Masatoshi Hori[1], Shigeto Komatsubara[2], Shinji Onose[3], Oki Higuchi[4], Teruo Miyazawa[5], Kiyotaka Nakagawa[6]

[1]Tohoku University, Japan, [2]Tohoku University, Japan, [3]Tohoku University, Japan, [4]PROJECT M, Japan, [5]Tohoku University, Japan, [6]Tohoku University, Japan

1-Deoxynojirimycin (DNJ), a constituent of mulberry, is a potent α-glucosidase inhibitor expected to be useful in the diet of diabetic patients. In this study, we compared the DNJ concentrations in 5 silkworm tissues, hemolymph, skin, gut, silk gland, and gut content, and investigated concentration changes during the growth of silkworms. Concurrently, we also investigated 2 other iminosugars, 2-O-α-D-galactopyranosyl-DNJ (GAL-DNJ) and fagomine. These iminosugars possess some α-glucosidase inhibitory activity or have other unique effects. The highest concentrations of DNJ and fagomine were obtained from 2-day-old third-instar larvae, and the concentrations decreased as development progressed. GAL-DNJ concentrations were very low in all developmental stages. Among the silkworm tissues, hemolymph contained the highest concentrations of DNJ and fagomine. The DNJ concentrations in hemolymph were extremely high, reaching approximately 10-fold higher than that of the entire silkworm body. The GAL-DNJ concentration in the gut content was the highest among the silkworm tissues, but the concentration was lower than that of mulberry leaves. These results suggest that when silkworms receive iminosugars from mulberry leaves, DNJ and fagomine are absorbed in intact forms into the hemolymph. However, GAL-DNJ is absorbed in a degalactosyl form into the hemolymph. Furthermore, we analyzed the iminosugar concentrations in the larvae of 2 other mulberry-feeding moths, Hyphantria cunea and Thanatarctia imparilis. The concentrations of these 3 iminosugars in both moth larvae were much lower than those in mulberry leaves. It was believed that these larvae immediately excreted these iminosugars without accumulating them. The accumulation of iminosugars may be specific to silkworms.

Keywords:*silkworm, mulberry, 1-deoxynojirimycin, iminosugar, fagomine, 2-O-α-D-galactopyranosyl-DNJ, diabetes, antidiabetic*

Digestive environment in the midgut of the xylophagous higher termite, *Nasutitermes takasagoensis*

Gaku Tokuda[1], Masaru Hojo[2], Rohitha P Kumara[3], Seikoh Saitoh[4], Hiroaki Aoyama[5], Hirofumi Watanabe[6]

[1]University of the Ryukyus, Japan, [2]University of the Ryukyus, Japan, [3]University of the Ryukyus, Japan, [4]University of the Ryukyus, Japan, [5]University of the Ryukyus, Japan, [6]National Institute of Agrobiological Sciences, Japan

The xylophagous higher termite Nasutitermes takasagoensis is though to digest cellulose primarily in the midgut. To further explore the detailed cellulolytic system in the midgut of N. takasagoensis, we performed immunohistochemistry and digital light microscopy to determine distributions of cellulolytic enzymes in the midgut as well as the luminal volume to estimate the total cellulolytic activity in the midgut. Although cellulolytic enzymes were uniformly produced in the midgut epithelium, the concentration of endo-β-1,4-glucanase activity and luminal volume in the midgut were comparable to those of the wood-feeding lower termite Coptotermes formosanus, which digests cellulose with the aid of hindgut protists. However, the size of ingested wood particles in N. takasagoensis was considerably larger than that in C. formosanus. Nevertheless, it is possible that the cellulolytic system in the midgut of N. takasagoensis hydrolyzes highly crystalline cellulose to a certain extent. To understand a variety of molecules involved in the digestive system in the midgut, we performed a trascriptome analysis with a pyrosequencer, 454 GS junior using mRNA extracted from the midgut. So far, no mRNAs encoding lignocellulolytic enzymes other than β-glucosidases belonging to the glycoside hydrolase family 1 (GH1) and endo-β-1,4-glucanases affiliated with GH9 have been identified from the midgut transcriptome. On the other hand, in addition to cellulases, the midgut abundantly contains mRNAs that encode chitinases and proteinases, which might play roles in degradation of fungal commuity on the surface of ingested wood particles and/or of termite bodies ingested through cannibalism.

Substrate vibrations mediate avoidance behavior via the femoral chordotonal organ in a cerambycid beetle, *Monochamus alternatus*

Takuma Takanashi[1], Midori Fukaya[2], Hiroshi Nishino[3]

[1]Forestry and Forest Products Research Institute, Japan, [2]The University of Tokyo, Japan, [3]Hokkaido University, Japan

Most insects can detect substrate vibrations in order to recognize predators and conspecifics. However, little is known about how coleopteran insects respond to vibrations. We investigated vibrational responses and associated sense organs in the Japanese pine sawyer beetle, Monochamus alternatus (Coleoptera: Cerambycidae). This beetle showed behavioral responses, such as startle responses and stridulation from a stationary position, to vibrations with low frequencies below 1 kHz. We identified for the first time the femoral chordotonal organ (FCO) of a coleopteran species. The main body of the FCO contained multiple sensory neurons and was distally connected to the proximal tibia via an apodeme. We subsequently showed that beetles with ablated FCOs did not freeze in response to low-frequency vibrations during walking whereas intact beetles froze. These results indicated that the FCO is responsible for detecting low-frequency vibrations and mediating the freezing behavior. We discuss the behavioral significances of vibrational responses in M. alternatus with respect to predator avoidance and conspecific recognition.

Developmental expression profiles of sex-related genes and RNA interference of transformer in *Bactrocera dorsalis*

Chia-Hsin Li[1], Shu-Mei Dai[2], Cheng Chang[3]

[1]National Chung-Hsing University, Taiwan, [2]National Chung-Hsing University, Taiwan, [3]National Chung-Hsing University, Taiwan

Bactrocera dorsalis (Hendel) is an important insect pest that needs to be effectively controlled in Taiwan. To understand more about its sex-specific regulation, we analyzed transformer (tra), transformer-2 (tra-2), doublesex (dsx), and yolk protein gene (yp1) in this oriental fruit fly using RT-PCR. Expression patterns of these genes fluctuated during different developmental stages. High levels of Bdtraf were present in both unfertilized and fertilized eggs. In both larval and pupal stages, the expression of these sex-related genes was relatively low in comparison with that in adult stage. After eclosion, the expression of Bdtraf, Bddsxf and Bdyp1 in female and the expression of Bddsxm in male increased gradually. These phenomena imply that these gene products may have critical physiological functions in sex differentiation pathways. For Bdtra functional assay using RNA interference (RNAi), double-strand RNA covering exon 2 to exon 4 was prepared and injected into 68 early pupae. Among the 19 females that emerged, seven showed deformed ovipositors without egg laying, yet normal ovaries were found upon dissection. All RNAi treated males that emerged had normal external genital organs and spermaries. These observations support that sex determination occurs in early developmental stage. Repressing Bdtra at pupal stage would subsequently produce similar effect on the downstream Bddsx, leading to morphological changes in females.

Cannibalism modifies metabolic fingerprint and growth rate in *Helicoverpa armigera*

Luis Fredd Leonardo Vergara Montalvo
RIKEN, Japan

Cannibalism is known in many insect species, yet its impact on insect metabolism has not been investigated in detail. This study assessed the effects of cannibalism on the metabolism of 4th-instar larvae of Helicoverpa armigera. Two groups of larvae were analyzed: one group fed with artificial plant diet, the other group fed with 4th-instar larvae of H. armigera. Water-soluble organic compounds present in each group were analyzed using one- and two-dimensional nuclear magnetic resonance (NMR). Multi-element analyses of each group were carried out by inductively coupled plasma/optical emission spectrometry. Chemical fingerprints analyzed using principal component analysis (PCA) were statistically different between cannibals and herbivores. In the case of NMR data, a list of compounds potentially present in each sample was produced by matching signals with a database of authentic compounds. Cannibalism reduced larval size and PCA showed that some NMR signals contributed more than others to the total variance of the chemical fingerprints. To identify essential nutrients for the development of larval stages of H. armigera, future experiments are proposed to evaluate if deprivation of these compounds can explain the small size of cannibals.

Sex pheromone desaturase functioning in a primitive *Ostrinia* moth is cryptically conserved in congener's genomes

Takeshi Fujii[1], Yukio Ishikawa[2]

[1]Tokyo University, Japan, [2]Tokyo univ., Japan

(E)-11- and (Z)-11-tetradecenyl acetate are the most common female sex pheromone components in Ostrinia moths. The Δ11-desaturase expressed in the pheromone gland (PG) of female moths is a key enzyme that introduces a double bond into pheromone molecules. A single Δ11-desaturase of Ostrinia nubilalis, Onub Z/ E11, has been shown to produce an ~7:3 mixture of (E)-11- and (Z)-11-tetradecenoate from the substrate tetradecanoate. In contrast, the sex pheromone of Ostrinia latipennis, a primitive species of Ostrinia, is (E)-11-tetradecenol. This pheromone is unique in that it is not acetylated, and includes no Z isomer. In the present study, through the cloning and functional analysis of a PG-specific Δ11-desaturase in O. latipennis, we showed that the absence of the Z isomer in the pheromone is attributable to the strict product specificity of the Δ11-desaturase in this species, LATPG1. Phylogenetic analysis revealed that LATPG1 was not closely related to Onub Z/ E11. Rather, it was closely related to retroposon-linked cryptic Δ11-desaturases (ezi-Δ11) found in the genomes of O. nubilalis and Ostrinia furnacalis. Taken together, the results showed that an unusual Δ11-desaturase is functionally expressed in O. latipennis, although the genes encoding this enzyme appear to be cryptic in congeners.

cDNA cloning and mRNA expression of heat shock proteins in *Oxya chinensis*

Yaping Guo[1], Yuping Zhang[2], Huimin Yang[3], Jianzhen Zhang[4], Enbo Ma[5]

[1]Shanxi University, China, [2]Shanxi University, China, [3]Shanxi University, China, [4]Shanxi University, China, [5]Shanxi University, China

Heat shock proteins (Hsps) are a class of quick response proteins when insects are exposed to certain environmental stress. As a molecular marker in ecological toxicology, Hsps is more sensitive than the traditional biological indicators. The rice grasshopper, O.chinensis (Orthoptera: Acridoidea) is one of the important agricultural pests of rice. In this study, four full-length cDNA sequences of hsps genes were acquired from O.chinensis. They were glucose-regulated protein (OcGrp78), heat shock protein 70 (Ochsp70), heat shock protein 90 (Ochsp90), and heat shock protein 40 (Ochsp40), respectively. The mRNA expression in different tissues and developmental stages of rice grasshopper were determined under normal growth conditions in O.chinensis. The results showed that these four hsps appeared differential expression patterns in tissue distribution and during developmental stages. In addition, the expression profiles of these four hsps genes were investigated when insects were treated with Cd. The results suggested that Cd acute injection could induce the expression of OcGrp78, Ochsp70, Ochsp90, and Ochsp40 in O.chinensis, Ochsp70 was the most sensitive response gene when insects exposed to Cd acute stress. The results of chronic Cd exposure resulted in up-regulation of OcGrp78, Ochsp90, and Ochsp40 and down-regulation of Ochsp70. Our results inferred that OcGrp78, Ochsp70, Ochsp90 and Ochsp40 could be used as molecular markers of acute pollution of Cd, whether these hsps genes can be used as molecular markers of chronic Cd pollution remains to be elucidated.

Transcriptomic analysis of juvenile hormone biosynthetic organ in *Bombyx mori*

Toru Togawa[1], Kazuei Mita[2], Yuki Nakamura[3], Toshiki Namiki[4], Hiroaki Noda[5], Tetsuro Shinoda[6]

[1]Nihon University, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]National Institute of Agrobiological Sciences, Japan, [4]National Institute of Agrobiological Sciences, Japan, [5]National Institute of Agrobiological Sciences, Japan, [6]National Institute of Agrobiological Sciences, Japan

Juvenile hormone (JH) is a lipophilic hormone involved in various aspects such as development, reproduction, and polymorphism. JH is produced from Acetyl-CoA and Propyonyl-CoA in corpora allata (CA) in larvae of silkworm, Bombyx mori. In the JH-biosynthetic pathway, 13 steps of biochemical reaction have been predicted. Ten genes involved in the pathway have been already identified, but three are still uncertain. In order to identify these three genes we performed transcriptomic analysis for corpora cardiaca (CC)-CA complexes using DNA microarray, and compared the results with those of other tissues. In order to cover the transcriptome of CA, we first constructed and sequenced cDNA libraries of CC-CA complex, and clustered the obtained ESTs to establish representative sequences. Using EST clusters as well as predicted genes from B. mori genome, we designed a custom-made 44k DNA microarray for B. mori. The total RNA isolated from CC-CA of day-2 fourth instar larvae, which produce JH actively, and other tissues were analyzed with the microarray. Known JH-biosynthetic genes showed consistent expression with the previous reports, showing the reliability of this study. We found many genes expressed selectively and abundantly in CC-CA complexes. These genes are possibly involved in JH biosynthesis or other CC/CA functions; especially genes encoding for catalytic activities are expected to complete the JH-biosynthetic pathway.

cDNA cloning, thermal regulation and developmental expression of five heat shock protein genes in the western flower thrips, *Frankliniella occidentalis*

Haihong Wang[1], Zhongren Lei[2]

[1]*Chinese Academy of Agricultural Science, China,* [2]*Chinese Academy of Agricultural Science, China*

The western flower thrips, Frankliniella occidentalis is a highly invasive pest that is able to exploit many crops across a wide range of environmental conditions. Five full-length cDNAs of heat shock protein (HSP) genes (fo-hsp90, fo-hsp70, fo-hsp60, fo-hsp40 and fo-hsp28.9) were cloned from F. occidentalis and their expression was investigated in relation to cold shock, heat shock, and development using real-time quantitative PCR. All five genes showed high similarity to their counterparts in other species, indicating such genes are highly conserved. The expression of fo-hsps under thermal stress suggests that fo-hsp90, fo-hsp70, and fo-hsp28.9 are both cold- and heat-inducible, fo-hsp40 is only heat-inducible, and fo-hsp60 is thermal-uninducible. For each of the thermal-inducible fo-hsps, the maximal level of induction by heat stress was much higher than that by cold stress. In terms of expression in relation to development, the mRNA level of both fo-hsp90 and fo-hsp60 peaked at stages Larva 1 and Larva 3, yet decreased at stage Larva 2. The moderately high level of fo-hsp40 at stage Larva 1 decreased at stage Larva 2 but then peaked at stage Larva 3. Both fo-hsp70 and hsp28.9 maintained similarly low levels at both stages Larva 1 and Larva 2, and then peaked at Larva 3. However, mRNA level of all five fo-hsps decreased with development of propupae, pupae and adult. These results indicated that, in addition to thermal responses, all the five fo-hsps are involved in development.

Functional genes for juvenile hormone degradation in insects

Takuya Tsubota[1], Hideki Sezutsu[2], Takahiro Shiotsuki[3]

[1]National Institute of Agrobiological Sciences, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]National Institute of Agrobiological Sciences, Japan

Juvenile hormones (JHs) play important roles in the regulation of a number of physiological processes. JH titer is regulated by the control of its synthesis and degradation. Mainly two groups of enzymes are known to degrade JHs: JH-specific epoxide hydrolase (JHEH) and JH-specific esterase (JHE). To date, functional analysis of jheh- and jhe-related genes is yet carried out. In this study we attempted to evaluate the related genes of jhehs and jhes in two model insects, silkworm Bombyx mori and red flour beetle Tribolium castaneum. The search of the genomic sequence revealed that both species have five or six jheh-related genes. We found that multiple jheh-related gene products in both species could degrade JH efficiently, suggesting that one insect species have multiple JHEHs. Since each jheh-related gene was revealed to be expressed in tissue-specific manner, it is supposed that JHEHs regulate JH titer separately in each tissue. On the other hand, a large number of carboxylesterase genes were identified in the genome of both species: seventy-three for B. mori and forty-eight for T. castaneum. We investigated the enzymatic activity of seven JHE-related proteins in B. mori. However, no protein could degrade JH efficiently besides authentic JHE, suggesting that B. mori has only one JHE. Taking into consideration the previous study that JHEs hydrolyze JH in a reversible reaction whereas JHEHs convert JH to an irreversibly hydrolyzed product, our results indicate that the regulation of JH titer by JHEH and JHE is performed in a distinct manner in the organism.

A new coelomic gregarine parasite from the ghost moth, *Thitarodes pui* (Lepidoptera: Hepialidae)

Zixuan Sun[1], Wenjing Wu[2], Guren Zhang[3]

[1]Sun Yat-sen University, China, [2]Sun Yat-sen University, China, [3]Sun Yat-sen University, China

Gregarines, a variety of apicomplexan parasites, inhabit the intestine, coelom or reproductive vesicle of invertebrates including insects. Recently, we discovered a coelomic gregarine parasite from Thitarodes pui distributed at 4,156~4,600m in the Tibet Plateau. The ghost moth is known as a host species of entomopathogenic fungus Ophiocordyceps sinensis with medical and economical importance. Visible gregarine gametocysts were found in the coelom of T. pui adult hosts, containing tens of thousands of biconical oocysts. In this work, lots of trophozoites were found in the intestinal lumen of T.pui larvae fed with 10^3 oocysts/larva. Young trophozoites were characterized by a protomerite-deutomerite septum and a flowerlike epimerite. The septum was lost in mature trophozoites (obovoid, 40~100 μm). Morphological characters of oocysts and trophozoites suggest that the gregarine species is closely related to the genus Paraschneideria, which is consistent with previous phylogenetic analysis inferred from SSU rDNA sequences.

Effects of temperature stress on tropical insects: A case study with the brown planthopper *Nilaparvata lugens* (Stal)

Jiranan Piyaphongkul[1], Jeremy Pritchard[2], Jeff Bale[3]

[1]University of Birmingham, United Kingdom, [2]University of Birmingham, United Kingdom, [3]University of Birmingham, United Kingdom

Nilaparvata lugens (Stal) is the most serious rice pest and widely distributed across Asia. Experiments were carried out to determine the effects of heat stress on nymphs and adults of N. lugens by measuring critical thermal maximum (CTmax), heat coma temperature (HCT) and upper lethal temperature (ULT50). Further experiments investigated the ability of the insect to acclimate at low (15°C) and high temperatures (30oC) compared with the standard rearing regime (23°) by determining critical thermal minimum (CTmin), CTmax, chill coma temperature (CCT), HCT, lower lethal temperature (LLT50) and ULT50. Nilaparvata lugens also showed changes in their thermal tolerance after acclimation. When the rearing temperature was decreased from 23 to 15oC the LLT50 decreased from 2.3±0.4 to 0.5 ±0.4°C in nymphs and from 0.9±0.5 to -2.7±0.4°C for adults. The CTmin was similarly decreased from 15.3±0.3 to 12.5±0.3, 13.1±0.4 to 8.1±0.2 and 12.9±0.4 to 8.8±0.2°C; and the CCT from 6.7±0.2 to 6.2±0.2, 2.1±0.2 to -1.2±0.3 and 2.6±0.2 to -0.3±0.2°C for nymphs and adult females and males. With high temperature acclimation at 30°C the ULT50 increased from 41.8±0.1 to 42.9±0.1 and 42.5±0.1 to 43.6±0.1°C for nymphs and adults, the CTmax from 34.9±1.3 to 37.2±0.1, 37.0±1.0 to 37.3±0.1 and 37.4±0.7 to 37.7±0.1 and the HCT from 37.7±1.3 to 41.0±0.3, 43.4±1.7 to 45.0±0.1 and 42.0±1.8 to 43.2±0.5°C for nymphs and adult females and males. The results indicate that nymphs of N. lugens are currently living at temperatures close to their upper thermal limits, and that acclimation ability is greater at low than at high temperature.

The boule gene is required for spermatogenesis in the haploid male of the sawfly, *Athalia rosae*

Kazuki Sekine[1], Masatsugu Hatakeyama[2]

[1]National Institute of Agrobiological Sciences, Japan, [2]National Institute of Agrobiological Sciences, Japan

Most hymenopterans have haplo-diploid sex determination system in which female is diploid and male is haploid. Diploid females produce haploid eggs with reduction of genome sets, whereas haploid males produce haploid sperm without reduction of genome set. Therefore, maturation divisions similar to mitosis, not meiosis occurs in the spermatogenesis. The boule (bol) gene, a member of the DAZ family gene plays an important role in meiosis in a spermatogenesis-specific manner by regulating translation of the twine (twe: cdc25 homologue gene) mRNA in Drosophila melanogaster (Maines and Wasserman, 1999). Interestingly, the bol homologous gene is found in the genomes of hymenopterans such as Apis melifera and Nasonia vitripennis, though expression and function of this gene is unknown in this group (Schurko et al., 2010). In this study, we examined whether the bol gene is actually expressed and functions during spermatogenesis in haplo-diploid insects using the sawfly, Athalia rosae. First, we cloned and identified two alternatively spliced cDNAs of the bol homologues (Arbol-1, 2), and one cDNA of the cdc25 homologue (Arcdc25). It was revealed by RT-PCR that the Arbol-1 was expressed exclusively in the testis during the maturation division, and Arbol-2 was expressed not only in the testis, but also ovary and somatic tissues. Larval RNAi of Arbol and Arcdc25 resulted in the similar phenotypes: abnormal spermatogenesis and lack of mature sperm. Therefore, our results indicate that the Arbol gene is essential for the spermatogenesis of haploid males in which reductional divisions do not take place.

Production of human beta defensin (DEFB) -1, 2, 3 and LL37 using baculovirus expression system.

Mai Fukushima[1], Kazuhiro Iiyama[2], Jae-Man Lee[3], Jun Yamashita[4], Hiroaki Mon[5], Masutaka Furue[6], Gaku Tsuji[7], Takahiro Kusakabe[8]

[1]Kyushu University, Japan, [2]Kyushu University, Japan, [3]Kyushu University, Japan, [4]Kyushu University, Japan, [5]Kyushu University, Japan, [6]Kyushu University, Japan, [7]Kyushu University, Japan, [8]Kyushu University, Japan

There are many pathogenic microorganisms on human skin, but natural immunity prevents them from invading into the body. Beta-defensin (DEFB) and LL37, antimicrobial peptides, play a role in innate immunity on human epidermis and in maintaining our health. For example, immunosuppressant used for transplant surgery often causes skin disease by decreasing innate immunity. This suppression is a matter of grave concern in medical practice, and it is urgently necessary to develop a technique for preventing skin disease caused by these drugs. DEFB and LL37 are suggested to be the candidate molecules for this purpose. However, it is difficult to express DEFB and LL37 by bacterial protein expression system because they have antimicrobial activity. On the other hand, the antimicrobial activity may not influence protein expression in silkworm-baculovirus expression system. In this study, we constructed 4 distinct expression vectors of antimicrobial peptides, DEFB1, 2, 3 and LL37, respectively and expressed them by silkworm-baculovirus expression system. The recombinant proteins were purified by Ni-affinity chromatography to purify recombinant proteins. Purified recombinant DEFB2 had antimicrobial activity against E. coli and P. aeruginosa. Then their expression levels, yields and activities are compared.

Genome-wide analysis for chemoreceptor genes in an insect-phoretic nematode, *Bursaphelenchus xylophilus*

Kazuko Tsuchihara[1], Takuma Takanashi[2], Mattias Larsson[3], Taisei Kikuchi[4]

[1]Doshisha University, Japan, [2]Forestry and Forest Products Research Institute, Japan, [3]Swedish University of Agricultural and Life Sciences, Sweden, [4]Forestry and Forest Products Research Institute, Japan

Chemoreception governs essential aspects of the lives of many animals, including the search for mates and hosts. Animal genomes contain families of genes involved in chemoreception, i.e., olfaction and gustation. The pine wood nematode Bursaphelenchus xylophilus is an endoparasite that causes severe damage to pine forests. The nematode migrates via Monochamus cerambycid beetles. Recently, a high-quality draft genome sequence of the nematode was reported (Kikuchi et al. 2011, PLoS Pathogens). Based on sequence similarity, we investigated B. xylophilus chemoreception genes. Three classes of potential chemoreceptors -gustatory receptors, serpentine receptors, and others- were characterized in B. xylophilus by comparison to chemoreceptors in Caenorhabditis nematodes and insects. The serpentine receptors of B. xylophilus exhibited extensive divergence and duplication. The gustatory receptors represent an unusual chemosensory gene family that share a common origin with insect gustatory receptors; the family has remained small in nematodes but has expanded substantially in insects.

Possible roles of cuticular lipids in mating behavior of *Papilio polytes* (Lepidoptera: Papilionidae)

Hisashi Omura[1], Taro Noguchi[2]

[1]*Hiroshima University, Japan,* [2]*Hiroshima University, Japan*

Many species of adult butterflies use wing pattern and coloration as the primary cues for mating (sexual recognition and interspecific discrimination), while particular species utilize also male-specific scents. Moreover, they may depend on other sensory cues when inhabiting together with other species possessing similar appearance and odor. Papilio polytes (Papilionidae) inhabits sympatrically with several species of swallowtail butterflies with similar coloration. Before copulation, the male adults were necessarily found to palpate the body and/or wing of mating partners using forelegs. This behavior may be to scrutinize cuticular substances of the partners. The cuticular lipid profiles of 3-d-old adults were compared among P. polytes and its three related species P. protenor, P. macilentus, and P. helenus. GC-MS analyses revealed that the four species had different lipid compositions, in which linear hydrocarbons with 23?31 carbon atoms and hexadecanoic acid were identified as the common major components. P. polytes and P. protenor were sexually dimorphic in lipid composition; however other two species were sexually monomorphic in it. These results suggest that their cuticular lipids serve as chemical signals to express species and sex of swallowtail adults. P. polytes males have two types of sensilla trichodea (LST and MST) on the foreleg tarsi. The presence of a terminal pore in LST and MST indicates these potential functions as gustatory sensilla. Electrophysiological recording clarified that aqueous solutions of cuticular lipids elicited clear responses from half of LST, suggesting that the males could perceive the cuticular lipids of mating partners during palpation.

Effects of eye-removal on the photoperiodic response of the two-spotted spider mite, *Tetranychus urticae*

Yuichi Hori[1], Yuko Kawakami[2], Sakiko Shiga[3], Hideharu Numata[4], Shin G. Goto[5]

[1]Osaka City University, Japan, [2]Osaka City University, Japan, [3]Osaka City University, Japan, [4]Kyoto University, Japan, [5]Osaka City University, Japan

The photoperiodic regulation of seasonal events, such as induction or termination of diapause, is important in life cycles of mites. To receive photoperiodic information from the environment, mites must be equipped with photoreceptors. These can be either retinal receptors in the visual system, or nonvisual extraretinal photoreceptors. The predacious mite Amblyseius potentillae, in which ocelli are absent, shows a clear photoperiodic response, clearly indicating involvement of extraretinal photoreceptors in photoperiodism in the mite. In mites equipped with ocelli, however, involvement of retinal photoreceptors in photoperiodism has not been investigated. The two-spotted spider mite Tetranychus urticae possesses two pairs of ocelli. Adult females of this species terminate diapause in response to long days. To see whether the ocellus eyes function as photoperiodic photoreceptors in T. urticae, we removed the eyes with a laser ablation system. When intact mites in diapause were kept under long-day conditions after exposing to a low temperature they terminated diapause, whereas they remained in diapause when they were kept under short-day conditions after low temperature exposure. When both anterior and posterior eyes were bilaterally removed, mites did not terminate diapause even when they were kept under long-day conditions. In contrast, mites showed a clear photoperiodic response in diapause termination, when only anterior eyes on both sides were removed. These results indicate that both anterior and posterior eyes or only posterior eyes function as photoreceptors in photoperiodic termination of diapause in T. urticae.

The occurrence of cell death mechanisms during follicular atresia induced by nutritional deprivation in *Dipetalogaster maxima* (Hemiptera: Reduviidae), a vector of Chagas' disease.

Silvina Andrea Aguirre[1], Patricia Pons[2], Beatriz Patricia Settembrini[3], Edilberto Rene Rubiolo[4], Lilian Etelvina Canavoso[5]

[1]Universidad Nacional de Cordoba, Argentina, [2]Universidad Nacional de Cordoba, Argentina, [3]CONICET, Argentina, [4]Universidad Nacional de Cordoba, Argentina, [5]Universidad Nacional de Cordoba, Argentina

In insects, unfavorable physiological or nutritional conditions promote changes in the ovaries, which, in turn, elicit the atresia of some terminal follicles and oocyte resorption. Although recent studies in some species indicate that during atresia, the follicular and/or nurse cells can be eliminated by different cell death mechanisms, these events were scarcely explored in Triatominae. The aim of this work was to investigate the cell death mechanisms operating during follicular atresia induced by nutritional deprivation in Dipetalogaster maxima, a vector of Chagas' disease. For the study, we performed light, fluorescence and electron microscopy, TUNEL assays, western blot and immunofluorescence. The results showed that, in D. maxima, morphological changes during follicular atresia were established gradually. At early atresia, follicular cells exhibited apoptotic nuclei, DNA fragmentation and the presence of activated caspase-3 proteases. At late follicular atresia, cellular changes were more pronounced, and cytoplasm vacuolization and abundant autophagic vacuoles were clearly observed. At this stage, an intense fluorescence pattern of LC3-II, a marker of autophagy, and ultrastructural features compatible with necrosis were observed. Results showed for the first time in a hematophagous insect the occurrence of apoptosis, autophagy and necrosis operating during follicular atresia. Whereas apoptosis played a major role during the early atresia, autophagy and necrosis seemed to be more relevant at late stages of the process. It was shown that follicular atresia in D. maxima is a complex process, signed by biochemical and cellular changes which correlate with the time elapsed since the instauration of atresia.

Functional analysis of β-ATP synthase as a lipophorin-binding protein in the midgut of *Panstrongylus megistus* (Hemiptera: Reduviidae)

Leonardo Luis Fruttero[1], Celia Regina Carlini[2], Edilberto Rene Rubiolo[3], Lilian Etelvina Canavoso[4]

[1]Universidad Nacional de Cordoba, Argentina, [2]Universidade Federal do Rio Grande do Sul, Brazil, [3]Universidad Nacional de Cordoba, Argentina, [4]Universidad Nacional de Cordoba, Argentina

Lipophorin, the main insect lipoprotein, is a "reusable shuttle" that takes up or delivers lipids to tissues without being internalized and degraded. Thus, the process of lipid transfer involves the interaction of lipophorin with specific sites in the plasma membrane of the cells. Despite the relevance of this event in the physiology of the insects, the identification of non-endocytic lipophorin receptors is still lacking. The aim of this work was to characterize the role of the β subunit of the ATP synthase (β-ATPase) as a lipophorin-binding protein in the midgut membrane as well as its involvement in the transfer of lipids. Fifth instar nymphs of Panstrongylus megistus, an important vector of Chagas' disease in South America, were used for the experiments. This hematophagous species can take large blood meals containing a substantial amount of lipids. The results, obtained by ligand blotting followed by tandem mass spectrometry, identified the β-ATPase as a lipophorin-binding protein. The expression of β-ATPase, as measured by RT-PCR and western blot (WB), changed according to the physiological condition of the insects. Subcellular fractionation and WB detected β-ATPase in cellular membranes. The immunofluorescence analysis evidenced a partial co-localization of β-ATPase and lipophorin in the sub-epithelial layer of the midgut. Functional in vivo studies injecting an anti-β-ATPase antibody to block the lipophorin-β-ATPase interaction resulted in an important inhibition of the lipid transfer from lipophorin to the midgut. Taken together, these findings strongly suggest that β-ATPase plays a role as a non-endocytic lipophorin receptor in the midgut of P. megistus.

Follicular atresia in the hematophagous *Dipetalogaster maxima* (Hemiptera: Reduviidae): the involvement of acid phosphatase and cathepsin D

Jimena Leyria[1], Silvina Andrea Aguirre[2], Leonardo Luis Fruttero[3], Celia Regina Carlini[4], Edilberto Rene Rubiolo[5], Lilian Etelvina Canavoso[6]

[1]Universidad Nacional de Cordoba, Argentina, [2]Universidad Nacional de Cordoba, Argentina, [3]Universidad Nacional de Cordoba, Argentina, [4]Universidade Federal do Rio Grande do Sul, Argentina, [5]Universidad Nacional de Cordoba, Argentina, [6]Universidad Nacional de Cordoba, Argentina

In insects, unfavourable nutritional conditions induce biochemical and cellular changes in the ovarian tissue such as early degradation of vitellin (Vt), the main yolk protein, and the atresia of several follicles. In some species, the changes accomplished during atresia are elicited to promote the recycling of proteins to sustain younger follicles. In this study, we have explored the biochemical changes that take place during the process of follicular atresia induced by a nutritional deficit in Dipetalogaster maxima, a vector of Chagas' disease. We have emphasized in the roles of two acid hidrolases, cathepsin D (CD) and acid phosphatase (AP). The study included western-blot, the measurement of enzymatic activities, immunofluorescence as well as in vitro assays of Vt proteolysis employing specific inhibitors of CD and AP. Results demonstrated that proteolysis of Vt occurred gradually during the transition from vitellogenesis to follicular atresia. Higher activities of AP and CD were detected at early and late atresia, in comparison to pre-vitellogenesis and vitelogenesis. In vitro assays showed that AP is important in promoting Vt degradation, which in turn was mediated by CD. Altogether, the biochemical changes exhibited during follicular atresia in D. maxima could reflect the ability of the ovarian tissue to either, face another vitellogenic cycle if the nutritional status improve or increase female lifespam. The results also provide a better understanding of the biology of reproduction of Chagas' disease vectors which could be of potential use in vector control strategies.

Analysis of the AA-NAT (aralkylamine N-acetyltransferase) expression in different tissues during development of the cotton leaf worm, *Spodoptera littoralis*

Piotr Bebas[1], Joanna Kotwica-Rolinska[2], Evelin Witkowska[3]

[1]Uniwersity of Warsaw, Poland, [2]University of Warsaw, Poland, [3]University of Warsaw, Poland

Melatonin has been detected in organisms representing all phyla and it plays crucial role as mediator of the photoperiodic information. However in contradistinction to vertebrates the physiological role and metabolism of melatonin in insects is still poorly understood. Moreover some reports show, that in contrast to the organs of vertebrates, in which melatonin rises during the night, in examined insects tissues melatonin peak occurs during the day. These changes are an effect of the daily activity of the key enzyme in melatonin biosynthesis pathway, the aralkylamine N-acetyltransferase (aaNAT). In several studies it has been also shown that the insect aaNAT has at least two isoforms with different activities dependent on the pH. Here we show temporal patterns of the aaNAT activity in various larval and adult organs of the cotton leaf worm. Our data indicate differences of the diurnal aaNAT activity in all examined organs that is strongly dependent on the pH. Additionally we demonstrate differences between day and night expression patterns of the aaNAT gene. It seems that all tissues of the cotton leaf worm larvae and adults have their own and unique temporal pattern of the aaNAT gene expression and enzyme activity.

A genome-wide survey for RNAi genes in rice brown planthopper, *Nilaparvata lugens* (Hemiptera: Delphacidae)

Haijun Xu[1], Xuechao Zhang[2], Chuanxi Zhang[3]

[1]Zhejiang University, China, [2]Zhejiang University, China, [3]Zhejiang University, China

As an evolutionarily conserved gene-regulatory mechanism, RNA silencing occurs in a wide variety of eukaryotic organisms. In brown planthopper N. lugens, a major rice pest in Asian, available studies indicated that this species is amenable to systemic RNAi by approaches of delivering dsRNA either by microinjection or by feeding. Understanding the RNAi mechanism in this species might help us employ this technique to explore its biological features and control this pest in agriculture. The completed genomic sequence of N. lugens allowed us to comprehensively investigate the repertoire of genes involved in RNAi pathway by comparison with homolog genes from fruit fly D. melanogaster, red flour beetle T. castaneum and nematode C. elegans. Our analysis illustrated that the N. lugens genome encodes all RNAi core components and some genes implicated in systemic RNAi found in T. castaneum. The Brown planthopper retains one Drosha and two Dicer, four dsRNA binding motifs (dsRBM) proteins, five Argonaute proteins, two Snipper-like proteins, a sid-1-like protein and an systemic RNAi related RSD protein (RSD-3), but no RdRP-related protein was found as reported in other insects. A ScanProsite search revealed that some RNAi core components in N. lugens showed distinct features. A phylogenetic analysis of Dicer proteins implicated that N. lugens RNAi pathway is more similar to T. castaneum than D. melanogaster, the latter does not show a robust systemic RNAi response. The brown planthopper N. lugens might be a good model system to study the molecular mechanism of systemic RNAi in insects.

Transcriptomics of bacteriome and spermalege of the bedbug *Cimex lectularius*

Minoru Moriyama[1], Ryuichi Koga[2], Takahiro Hosokawa[3], Naruo Nikoh[4], Ryo Futahashi[5], Takema Fukatsu[6]

[1]National Institute of Advanced Industrial Science and Technology (AIST), Japan, [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan, [3]National Institute of Advanced Industrial Science and Technology (AIST), Japan, [4]The Open University of Japan, Japan, [5]National Institute of Advanced Industrial Science and Technology (AIST), Japan, [6]National Institute of Advanced Industrial Science and Technology (AIST), Japan

The bedbug Cimex lectularius (Hemiptera: Cimicidae) is an obligate blood-feeding exoparasite of human and other warm-blooded animals. In addition to its medical and hygienic importance, C. lectularius is known for its unique biological traits, which include the obligate nutritional mutualism with a vitamin-provisioning Wolbachia endosymbiont, and the peculiar mating habit called traumatic insemination. For these unique traits, novel insect organs, the bacteriome for endosymbiosis and the spermalege for traumatic insemination, have evolved in the lineage of bedbugs. We constructed cDNA libraries of the bacteriome and the spermalege of C. lectularius, and performed expressed sequence tag (EST) analyses of these peculiar insect organs. In total 4,480 ESTs were compiled as C. lectularius putative nuclear genes, which were assembled into 2,989 unique sequences (USs). The following ESTs and USs were identified from the different organs: 1,151 ESTs and 901 USs from the female whole body; 1,098 ESTs and 879 USs from the female bacteriome; 1145 ESTs and 783 USs from the male bacteriome; and 1,086 ESTs and 920 USs from the female spermalege. Although EST repertories were quite different between the female bacteriome and the male bacteriome, expression levels of antioxidant genes were commonly high in both the bacteriomes. The EST data of the spermalege library revealed a number of candidate genes of C. lectularius that are presumably relevant to its immune and defensive aspects. These EST data will provide a valuable genetic resource for understanding the developmental and evolutionary aspects of the novel insect organs. [Supported by BRAIN]

Juvenile hormone titer and JH signaling gene expressions during differentiation of neotenic reproductives in the termite *Reticulitermes speratus*.

Ryota Saiki[1], Kiyoto Maekawa[2]

[1]*University of Toyama, Japan,* [2]*University of Toyama, Japan*

The reproductive castes of termites include primary reproductives, which found a new colony, and neotenic reproductives which take over reproduction when primary reproductives die or are senescing. Neotenic reproductives usually differentiate from several stages of nymphs or workers and retain juvenile characteristics and functional gonads. Therefore, the organ formation of neotenic reproductives must be different from those of alates. However, developmental mechanisms during differentiation of neotenic reproductives are unknown. To clarify these mechanisms, we performed analyses on morphological and physiological changes during differentiation of neotenic reproductives of the termite Reticulitermes speratus. Morphological observations showed that wing-bud and compound-eye developments of the newly emerged neotenic reproductives were suppressed and significant ovarian development did not occur. However, vitellogenin gene expression levels in newly emerged neotenic reproductives were remarkably higher than those in nymphs. Next, we quantified the JH titer of each developmental stage using LC-MS. Our results showed that JH titers of newly emerged and mature neotenic reproductives were significantly higher than those of nymphs. Finally, JH signaling molecule (including Methoprene-tolerant which is a putative JH receptor gene) expression changes were analyzed by real-time quantitative PCR. The results showed that gene expressions in abdomen of neotenic reproductives were significantly higher than those in head and thorax. These results suggest that physiological changes occur soon after molts into neotenic reproductives, and their organ-specific developments are regulated by the organ-specific expression of the JH signaling pathway.

Molecular developmental mechanisms responsible for soldier-specific morphogenesis in the nasute termite *Nasutitermes takasagoensis*.

Kouhei Toga[1], Kiyoto Maekawa[2]

[1]*University of Toyama, Japan,* [2]*University of Toyama, Japan*

Social insects possess morphologically and behaviorally different castes, even though they have almost the same genetic backgrounds. Although juvenile hormone (JH) plays an important role in determining caste developmental fate, developmental mechanisms leading to morphological modifications are poorly understood. Termite soldier differentiation provides a tool for understanding the developmental mechanisms for morphological modification, because molts into presoldiers (the transitional stage prior to soldiers, possessing the fundamental morphologies of soldiers) can be induced artificially by JH application. Soldiers of the termitid subfamily Nasutitermitinae, one of the most derived termite groups, possess a long and horn-like frontal projection (nasus), an invaginated glandular structure in the head (frontal gland), and regressed mandibles. To investigate whether patterning gene and programmed cell death (PCD) are involved in soldier-specific organ formations of Nasutitermes takasagoensis, we performed RNAi for morphogenetic factors such as Distal-less (Dll) and TUNEL staining for the detection of PCD. RNAi showed that Dll was involved in nasus elongation, but not frontal gland formation. TUNEL staining showed that PCD was involved in mandibular regression. These results suggest that soldier-specific organ formation occurs by modifications of preexisting developmental mechanisms. Based on these results, together with analyses on other factors involved in cell proliferation (e.g. insulin signaling), we will discuss the molecular mechanisms of soldier-specific organ formation in termites.

Aim-then-shoot type of mechanisms involved in the jumping approach of potato moths to a sex pheromone source

Shin Tejima[1], Tomohiro Ono[2], Masayuki Sakuma[3]

[1]Kyoto University, Japan, [2]Kinjo Gakuin University, Japan, [3]Kyoto University, Japan

Male moths track an odor plume of sex attractant pheromone emitted by conspecific females. It is widely accepted that for flying moths, upwind flight is essential for tracking pheromone, and it is achieved during flight by detecting a visual flow, termed optomotor anemotaxis. However, pheromonally excited males of potato moth, Phthorimaea operculella, exhibit a series of intermittent short-straight flights, or jumps, while going upwind. It is hardly conceivable that they navigate themselves by employing the same mechanism as flying moths use. To analyze odor-conditioned anemotaxis of potato moth males, we constructed a flat wind tunnel sandwiched between a pair of glass plates, in which a plane of air flows from one side to the other. A computer-regulated valve system introduces pheromonally-permeated air as pulses into the air flow, thus it forms a series of odor bands separated by gaps of clean air. This enabled to give odor stimuli regularly to an insect regardless of its location in the wind tunnel. Path analyses revealed that males surged upwind when they encountered a pheromone pulse, and released casting with successive jumps when they lost odor. This behavioural pattern seems to be similar to that of flying moths. When the direction of the air flow was switched orthogonally, however, males could adjust course angle accordingly while they were on the ground. It is suggested that instead of optomotor cues, mechanosensory means might be adopted to detect wind direction by 'aim-then-shoot' mechanisms. Here we propose some evidence.

Diversification of photoreceptors in the compound eye of the birdwing butterfly, *Troides aeacus formosanus*

Pei-Ju Chen[1], En-Cheng Yang[2]

[1]*National Taiwan University, Taiwan,* [2]*National Taiwan University, Taiwan*

Electrophysiological recording in the compound eye of the birdwing butterfly, Troides aeacus formosanus, showed that there are 9 spectral types of photoreceptor with peak sensitivities at 370 nm, 390 nm, 450 nm, 510 nm, 540 nm, 550 nm, 580 nm, 610 nm, and 630 nm. The spectral sensitivities of some photoreceptors do not match to those predicted spectrum of a visual pigment, when fitting the theoretical pigment absorption curves to the recorded spectral sensitivities. The inspection of an intact eye under ultraviolet epi-illumination revealed that some ommatidia exhibit UV-induced fluorescence. The ommatidial heterogeneity is correlated with the red or yellow pigmentation around the rhabdom. Tuning of spectral sensitivities of photoreceptors could be due to the filtering effects by the fluorescing and perirhabdomal pigments in the Troides eye. In addition to the optical filtering effects, negative-going responses were observed, indicating that there are strong antagonistic electrical interactions at the level of photoreceptor. The variety of receptor types caused by the pigments filtering effects and electrical interactions in the Troides eye suggests that the Troides butterfly has a good ability on color discrimination.

Functional analysis of epigenetic regulation during embryogenesis of the cricket, *Gryllus bimaculatus*

Yuji Matsuoka[1], Tetsuya Bando[2], Taro Nakamura[3], Taro Mito[4], Sumihare Noji[5]

[1]The Tokushima University, Japan, [2]The University of Tokushima, Japan, [3]The Tokushima University, Japan, [4]The Tokushima University, Japan, [5]The Tokushima University, Japan

Epigenetic regulation is evolutionarily conserved mechanism to maintain correct gene transcriptions for proper developmental processes. In Drosophila embryos, Polycomb group (PcG) genes are one of the epigenetic factors and function in regulation of Hox gene expression after Gap genes expression is diminished. To elucidate the function of epigenetic regulation in development of Gryllus bimaculatus are phylogenetically basal insect, we cloned three PcG genes, Gryllus homolog of Enhancer of zeste (E(z)), Polycomb (Pc) and Suppressor of zeste 12 (Su(z) 12) and performed RNAi. E(z)RNAi embryos were lethal at late stages showing defect in katatrepsis. In the RNAi-ed embryos, the Hox genes, Antennapedia, Ultrabithorax, abdominal-A and Abdominal-B, were ectopically expressed in the whole embryo body, while Sex combs reduced expression was reduced. The antenna, maxilla, labium and three-pair of thoracic legs showed homeotic transformation to the T3 leg, consistently with alteration of Hox gene expressions. Pc and Su(z)12 RNAi-ed embryos also were lethal and defected in katatrepsis, but homeotic transformation of appendages were not occurred. Reduction of trimethylated on hisotneH3 lysine 27 (H3K27me3), which is catalyzed by E(z), was observed in E(z)RNAi embryos but not in Pc and Su(z)12 RNAi-ed embryos. In Gryllus, only E(z)RNAi embryos showed alteration of Hox genes expression pattern as shown in fly and mouse PcG genes mutants, although Drosophila Pc and Su(z)12 mutants showed that. These results suggest that functions of PcG gene constituents, Su(z)12 and Pc, in regulating Hox genes were altered during insect evolution. Furthermore, in the basal Gryllus, PcG genes regulate katatrepsis, different from Drosophila.

Expansion of the odorant receptor family and reduction in the gustatory receptor family in the Hessian fly: - Adaptation to a stressful lifestyle?

Martin N. Andersson[1], Christer Lofstedt[2], Hugh Robertson[3]

[1]Lund University, Sweden, [2]Lund University, Sweden, [3]University of Illinois, U.S.A.

The Hessian fly (Diptera, Cecidomyiidae) is a serious pest of wheat in most wheat growing areas in the world. The short adult life (1-2 days) means that flies are forced to accomplish host and mate finding within a restricted timeframe, which puts a high demand on the chemical senses. The insect odorant receptors (ORs) and gustatory receptors (GRs) belong to a large superfamily of chemoreceptors. We annotated 122 ORs and 27 GRs from the Hessian fly genome. Compared to D. melanogaster and A. gambiae, we find drastic expansions of OR lineages in the Hessian fly. The largest expansion contains 71 Hessian fly ORs, and no OR from the other species. Many of these ORs share very high amino acid identity and are located close on chromosomes, indicating recent duplication events. In contrast, we found a considerable reduction in GRs, by at least half, relative to other genome-sequenced Diptera. Hessian fly contains all three CO2 receptors, but has a reduced set of sugar receptors. For both the ORs and GRs, the Hessian fly appears to have lost numerous lineages that might have been present at the base of the Diptera. The expanded OR-, but reduced GR repertoire, might have evolved as a result of specialization on a single host plant and utilization of a long-range sexual pheromone. Possibly when life is short, long-range cues predominate, as there might simply be no time to land on potential hosts or mates and evaluate their quality upon contact.

Changes In the expression of cell cycle markers in moth *Spodoptera littoralis* tissue after exposure to the juvenile hormone analog- Fenoxycarb

Agnieszka Suszczynska[1], Joanna Kotwica-Rolinska[2], Piotr Bebas[3], Marta Anna Polanska[4]

[1]University of Warsaw, Poland, [2]University of Warsaw, Poland, [3]University of Warsaw, Poland, [4]University of Warsaw, Poland

Physiological processes, including growth and development in insects are controlled by two major hormones: ecdysteroids and juvenile hormones (JHs) which regulate metamorphosis i.e. by acting on cell cycle and apoptosis in most tissues. Juvenile hormone analog (JHA)- fenoxycarb (the carbamate belonging to growth regulators) imitate the action of JH by binding to the same receptors finally causing disruption of insect development and reproduction. In this study we investigated effect of fenoxycarb on cell cycle markers in Egyptian cotton leaf worm Spodoptera littoralis tissues. Animals were treated with different doses of fenoxycarb and next kept in normal conditions for next 24 hours. Then, using the Real-Time quantitative PCR approach we tested the genes expression of cyclin A, cyclin C, cyclin T and Growth Arrest and DNA Damage (Gadd) in gonads, brains and Malpighian tubes, isolated from treated insects. Obtained data indicate that fenoxycarb increases expression of cell cycle markers in gonads, but decreases or does not change cell proliferation markers in the central nervous system and Malpighian tubes. Supported by NCN grant No. N N303 803340 to MAP.

RNA interference in the termite *Reticulitermes speratus*: a comparison of effect on silencing the hexamerin gene between single 21 nt siRNAs and a long dsRNA.

Shuji Itakura[1], Saho Tatsuuma[2], Toshihiro Teranishi[3], Kaya Hashizume[4], Miyu Kaneda[5]

[1]Kinki University, Japan, [2]Kinki University, Japan, [3]Kinki University, Japan, [4]Kinki University, Japan, [5]Kinki University, Japan

We had reported silencing of the hexamerin gene of R. speratus using a single 21 nt small interfering RNA. The single siRNA had been selected in order to avoid off-target effects that could be caused by using long dsRNA or a mixture of siRNAs of various lengths (15 - 25 bp) prepared by digestion of dsRNA. To confirm effectiveness of a single siRNA, three kinds of 21 nt siRNAs and a long dsRNA (585 bp) were prepared from the hexamerin sequence of R. speratus (AB371986). The target sequences for siRNAs (330-348, 2107-2125, 2273-2291 nt) were designed using the siRNA Target Designer program (http://www.promega.com/siRNADesigner/program/), while that for a long dsRNA (635-1219 nt) with low sequence similarity to sequences in the nucleotide databases was selected using BLASTN. The siRNA and dsRNA injection treatments (injection volume 2.3 nl, 3.0 ng) used to silence hexamerin caused moderate suppression of hexamerin gene expression in workers for 3 days after the injection. In 5 days, hexamerin gene expression recovered in workers injected with two kinds of siRNAs and a long dsRNA, while suppression continued in one of siRNA treatments. Hexamerin gene expression in workers injected with three kinds of siRNAs and dsRNA was recovered and rose about twice (a siRNA and a long dsRNA), 8 times (a siRNA), and 26 times (a siRNA) in 7 days after injection. Present study showed that single 21 nt siRNAs and a long dsRNA suppressed equally hexamerin gene expression in workers of R. speratus for three days after injection.

Molecular cloning and analysis of a novel beta-1,3-glucan recognition protein from the ghost moth, *Thitarodes pui* (Lepidoptera, Hepialidae)

Wenjing Wu[1], Zixuan Sun[2], Min Zhang[3], Chao Song[4], Guren Zhang[5]

Detection of pathogen surface molecules is the crucial first step of host defense reactions. Beta-1,3-glucan recognition proteins (βGRPs) are soluble pattern recognition proteins that bind to β-1,3-glucans from fungi cell walls and initiate immune responses in insects. A novel βGRP gene was cloned from the ghost moth Thitarodes pui, narrowly distributed at an altitude of 4,100 to 4,650 m in the Mt. Sejila of the Tibetan Plateau. The βGRP was classified into βGRP clade 4 in phylogenetic analysis and designated TpβGRPc. The full-length TpβGRPc cDNA (1,915 bp) has a 1,464 bp open reading frame encoding a protein of 488 amino acid residues including a 21 amino acid residues signal peptide, a 127 bp 5' untranslated region (UTR) and a 324 bp untranslated region in the 3' UTR with a 26 bp polyA tail. The calculated molecular mass of the mature protein is 52,596 Da with an estimated pI of 6.06. Tertiary structure of TpβGRPc contains two distinct regions. The N-terminal domain responsible for β-1,3-glucan binding affinity includes ten putative β-strands. The C-terminal domain shows a classical sandwich-like β-jelly roll fold that is similar to β-1,3-glucanases. In phylogenetic tree, TpβGRPs (TpβGRPa, TpβGRPb and TpβGRPc) formed a distinct and separate clade 4 in Lepidopteran βGRP family, which might ascribe to the local distribution of the homoneurous primitive ghost moth.

Influence of pymetrozine on feeding behaviors of four major rice sap-sucking insect pests using electrical penetration graphs

Yueping He[1], Juefeng Zhang[2], Jianming Chen[3], Li Chen[4], Jinliang Shen[5], Yu Cheng Zhu[6]

[1]Zhejiang Academy of Agricultural Science, China, [2]Zhejiang Academy of Agricultural Science, China, [3]Zhejiang Academy of Agricultural Science, China, [4]Zhejiang Academy of Agricultural Science, China, [5]Zhejiang Academy of Agricultural Science, China, [6]USDA-ARS, U.S.A.

Pymetrozine is a selective insecticide with the basic structure of a pyridine azomethine, and it is effective against sap-sucking insects. However, the mechanism of feeding inhibiting of pymetrozine to sap-sucking insects is still unknown. The results showed that pymetrozine primarily functioned as an antifeedant to cause starvation and death to Nilaparvata lugens, rather than neuro-toxicity. Pymeytrozine-treated insects died at a significantly slower speed than starvation-treated insects. Pymetrozine significantly inhibited phloem ingestion, and the inhibition was strongly dose-correlated. The phloem ingestion was totally suppressed when the pymetrozine concentration increased to 400 mg litre-1. Starvation caused by inhibition of phloem ingestion might be a major toxicity mechanism of pymetrozine. However, pymetrozine had no effect on the xylem ingestion. It is likely that pymetrozine-treated insects, could sustain for a while on water and limited nutrients from xylem ingestion before they died. On pymetrozine-free rice plants, Sogatella furcifera and Laodelphax striatellus showed a significantly less activity in phloem phases than N. lugens or Nephotettix cincticeps, while N. cincticeps exhibited relatively more xylem ingestion than N. lugens, S. furcifera and L. striatellus. On the plants treated with 100 mg litre-1 of pymetrozine, all four insect pests showed significant increases in total duration of non-probing and significant decreases in the activities in phloem tissue, and similar feeding behavior during the pathway and xylem phases. This revealed that their feeding behavior was disturbed by pymetrozine and exhibited similar patterns of sharp decline in activity in the phloem tissue and a significant increase the non-probing.

Positional cloning of the chocolate 2 (ch-2) gene controlling newly hatched larvae colour in silkworm, *Bombyx mori*.

Rui Zhang[1], Chengxiang Hou[2], Xinglin Mei[3], Anjiang Tan[4], Anying Xu[5], Yongping Huang[6], Muwang Li[7]

[1]Jiangsu University of Science and Technology, China, [2]Jiangsu University of Science and Technology, China, [3]Jiangsu University of Science and Technology, [4]Chinese Academy of Sciences, China, [5]Chinese Academy of Agricultural Sciences, China, [6]Chinese Academy of Sciences, China, [7]Chinese Academy of Sciences, China

Abstract: In the silkworm, many mutants exhibiting newly hateched larvae colour have been found. One of the most interesting mutants is ch-2(chocolate, 18-0.0). The body-color of newly hatched larvae in ch-2 homozygous individuals are reddish brown. To better understand the colour formation mechanism of newly hatched larvae in silkworm, we tried to isolate the gene responsible for ch-2 based on positional cloning. Seven polymorphic markers were selected from the SSR linkage maps (Miao et al, 2005). Fifty-Seven pairs of STS primers were designed according to the sequence of nscaf2901 on chromosome 18, and 12 of them had been found to be polymorphic between the parents, k04(ch-2) and p50. Using these primers, ch-2 had been mapped in a region of 300kb on nscaf2901 by using 477 backcross progenies. There are 8 predict genes in this region. They were all expressed as mRNA in embryo. After comparing the cDNA sequences of thes genes between p50 and k04, we found a deletion of 146bp in cuticular protein glycine-rich 6 (CPG6) (BGIBMGA008245) in K04 according to normal P50, we cloned the sequence and obtained a full length cDNA. Based on the cDNA sequence, we designed and synthesize siRNA to interfere the BmCPG6 gene expression in P50 embryo, and we found most of the colour of newly hatched larvae changed to chocolate. Based on these results suggest that a mutation in BmCPG6 gene causes the phenotype of ch-2.

Water physiology of vitellogenic follicles in *Bombyx mori*

Mariya Maruyama[1], Tomone Nagae[2], Masaaki Azuma[3]

[1]Tottori Univ, Japan, [2]Tottori University, Japan, [3]Tottori University, Japan

Ovarian follicles pass through a growth phase during which the developing oocyte endocytoses the vitellogenin and other yolk proteins for storage in its cytoplasm. It has long been recognized that an oocyte increases its size by water absorption during this process. We have raised a question whether an aquaporin (AQP: water channel) is necessary for oocyte swelling between onset and termination of oocyte maturation. By the immunoblotting test with three specific antibodies directed to each Bombyx AQP, we found the strong bands around 110-kDa, which appears to be the tetrameric nature of AQP-Bom3 [PRIP] from the developing ovaries (vitellogenic follicles). When sections of vitellogenic follicles from the female pupa (Day 6 ovary) were stained with anti-AQP antibody for Bombyx PRIP, the stain was localized at the periphery of an oocyte and not at any regions of follicular epithelium as well as the nurse cells. This AQP may have a role admirably suited to the egg growth. The other water-specific AQP (AQP-Bom1 [DRIP]) appeared at a certain type of yolk granules distributed in the cortex of an oocyte on the post-vitellogenic phase (Day 9-10 ovary). The significance of AQP-Bom1 in some yolk granules was unclear, but these data suggested that two water-specific AQPs function in developing ovaries of B. mori spatially and temporally.

Embryonic development of Zoraptera and its phylogenetic implication

Yuta Mashimo[1], Ryuichiro Machida[2]

[1]University of Tsukuba, Japan, [2]University of Tsukuba, Japan

Zoraptera is one of the least diverse and most poorly understood insects. Until now more than 10 different phylogenetic positions have been proposed. The term "Zoraptera problem" is coined to highlight the highly controversial status of the most enigmatic insect, after the "Strepsiptera problem". Recently, detailed morphological studies on Zoraptera have emerged, but information on its embryonic development is still lacking. In this background, we have started the embryological study of Zoraptera, using Zorotypus caudelli Karny. Embryonic development of Z. caudelli is characterized by the following features: 1) embryo anlagen with a pair of higher cell density areas, 2) embryogenesis of short germ band type, 3) embryo's elongation along the ventral surface, 4) parallel migration of embryo into the yolk after its full elongation on the egg surface, 5) revolution with embryo's anteroposterior axis reversed, and 6) egg tooth extraordinarily elongated on the head capsule. Zoraptera agrees with Polyneoptera, sharing the features 1), 3) and 4) with polyneopteran members, whereas it differs in embryogenesis from Paraneoptera, in which the embryo gradually immerses into yolk from its rear, elongating posterior, to take its position deep in the yolk. This may suggest that Zoraptera is a member of Polyneoptera, being not of Paraneoptera. Our recent studies on Zoraptera revealed close resemblances in egg structures (Mashimo et al., 2011) and male reproductive systems (Dallai et al., 2011) between Zoraptera and Eukinolabia (= Phasmatodea + Embioptera). The feature 6) "long egg tooth" as found in Zoraptera had been only reported in Embioptera (Jintsu, 2010)

Effect of entomopoxvirus infection on growth and metamorphosis of *Mythimna separata* larvae

Hirotoshi Kinjo[1], Jun Takatsuka[2], Takahiro Shiotsuki[3], Yasuhisa Kunimi[4], Madoka Nakai[5]

[1]Tokyo university of agriculture and technology, Japan, [2]Forestry and Forest Products Research Institute, Japan, [3]National Institute of Agrobiological Sciences, [4]Tokyo university of agriculture and technology, Japan, [5]Tokyo university of agriculture and technology, Japan

Insect viruses are among the most important parasitic natural enemies of lepidopteran insects. Virus-infected larvae show developmental defects including a prolonged larval period and a failure to pupate, but an overview of the mechanisms by which insect viruses regulate host development has not yet been established. Larvae infected with members of the Baculoviridae (double-stranded circular DNA viruses) fail to pupate because host ecdysteroids are inactivated by ecdysteroid UDP-glucosyltransferase (EGT), an enzyme that is encoded by most baculovirus genomes. However, entomopoxviruses (EPVs), which belong to the Poxviridae and possess a double-stranded linear DNA genome, also prolong the larval period and prevent host pupation, although no EPV has yet been found to encode EGT in its genome. Thus, EPVs are likely to have a different mechanism from baculoviruses to regulate host metamorphosis. In this study, the endocrinological regulation of a lepidopteran EPV, Mythimna separata EPV (MyseEPV), was examined. When M. separata larvae were inoculated at 4th instar with 104 MyseEPV occlusion bodies/larva, pupation was prevented and the insects died in the larval stage after prolongation of the larval period by an average of 6.95 days. The hemolymph of healthy and EPV-infected larvae was collected and the titers of juvenile hormone (JH) and ecdysteroids were measured. LC-MS measurement revealed that JH titers in MyseEPV-infected larvae in the final instar were higher than those in healthy larvae. Ecdysteroid titer was measured using anti-ecdysteroid serum by radioimmunoassay. The ecdysteroid titer in final-instar MyseEPV-infected larvae was lower than that in healthy larvae.

Identification of peptidyl factors modulating feeding behavior of the silkworm, *Bombyx mori*

Shinji Nagata[1], Hiromichi Nagasawa[2]

[1]Graduate school of the University of Tokyo, Japan, [2]Graduate school of the University of Tokyo, Japan

Phytophagous insects including a lepidopteran species such as the silkworm, Bombyx mori, exhibit regularly occurring feeding behavior. To identify factors involved in the regulation of insect feeding behavior, we established a bioassay to evaluate the activity of feeding initiation by measuring latency to the first bite after sample injection in starved Bombyx larvae. Feeding inhibitory activity was observed in the crude extracts of all examined tissues from Bombyx larvae. We then purified feeding-related factors from the extract of the Bombyx larval midgut because of its strongest activity. Four steps of purification by reversed-phase HPLC allowed us to isolate two peptidyl factors. Amino acid sequence analyses revealed that one was allatotropin composed of thirteen amino acid residues, and the other was a novel peptide composed of seventeen amino acid residues, designated GSRYa after the C-terminal sequence. We also examined the feeding activities of several synthetic peptides which have been identified comprehensively in silico using this bioassay. The results showed that five more peptidyl factors were related to feeding behavior in B. mori (allatostatin, myosuppressin, calcitonin-like diuretic hormone 31, short neuropeptide F, and tachykinin). In the present study, we also discuss how these peptidyl factors can modulate the feeding behavior in insects.

Ovarian development in females of *Triatoma sordida* Stal (Hemiptera: Reduviidae: Triatominae) under fasting conditions.

Claudia Susana Rodriguez[1], Silvina Andrea Aguirre[2], Julieta Nattero[3], Lilian Etelvina Canavoso[4], Liliana Beatriz Crocco[5]

[1]Universidad Nacional de Cordoba, Argentina, [2]Universidad Nacional de Cordoba, Argentina, [3]Universidad Nacional de Cordoba, Argentina, [4]Universidad Nacional de Cordoba, Argentina, [5]Universidad Nacional de Cordoba, Argentina

Triatoma sordida is a secondary vector of Trypanosoma cruzi - causative agent of Chagas disease - considered a species of epidemiological importance. It is often found in the peridomestic habitat and frequently invade and colonize human dwellings. The study of aspects of the reproductive capacity of these species is relevant for the relationship with colonization of new habitat. The object of the present work was to characterize through morphometric and histological studies the ovarian development in females of T. sordida in absence of food and mating, which were killed at different days post-ecdysis. Morphological changes of the ovaries were estimated by morphometric analysis of basal follicle of each ovariole and oocytes number for different phases of oogenesis. For the histological study the ovaries were embedded in paraffin, processed routinely for hematoxylin?eosin staining. The results indicate that T. sordida presents a quantitative pattern appropriate to identify the three phases of oogenesis. The mean length of basal follicle varied between different phases (0.358±0.096 mm pre-vitellogenesis, 0.638±0.331 mm, vitellogenesis and 1.929±0.136 mm choriogenesis). At the 2nd day post-ecdysis, 100% of the females showed pre-vitellogenic oocytes and 50% showed vitellogenic oocytes at the 4th day. The choriogenic and ovulation processes began at 8th day post-ecdysis. The morphological changes observed in the basal follicles were consistent with the results of histological analysis. These results would indicate that, at 6 days post-ecdysis, females of T. sordida without feeding have eggs ready to be oviposited.

Effect of the juvenile hormone on resistance against pathogen differs between sexes

Markus J. Rantala
University of Turku, Finland

Juvenile hormone is suggested to be a potential mediator in trade off between sexual signaling and immune defence and also trade off between mating and immunity in insects. Studies in a variety of insect taxons have found that juvenile hormone corrupts humoral and cellular immunity. However, studies using real parasites and pathogens are lacking so far. In this study, we tested if the administration of the juvenile hormone have effect on the resistance against an entomopathogenic fungi, Metharizium anisopliae by usingn the meal worm beetle, Tenebrio molitor, as a model species. In previous studies with T. molitor juvenile hormone has been found to reduce a major humoral immune effector-system (phenoloxidase) in both sexes and to reduce the encapsulation response in males. However, we found that juvenile hormone administration prolonged survival time after infection , but reduced survival time in females. Thus, juvenile hormone treatment enhances resistance against the entomopathogenic fungi in males but reduced in females. Results of this study show that the effect of the juvenile hormone on insect immunity may be more complicated than it has been previously thought. We also suggest, that there might be a trade off between specific and non-specific immunity, since in males juvenile hormone enhance specific immunity but corrupts non-specific immunity. Our study highlights the importance of using real parasites and pathogens in immunoecological studies.

Biological activities of juvenile hormone skipped bisepoxide (JHSB3) in the stink bug, *Plautia stali*

TOyomi Kotaki[1], Teshuro Shinada[2], Kanako Kaihara[3], Yasufumi Ohfune[4], HIdeharu Numata[5]

[1]National Institute of Agrobiological Sciences, Japan, [2]Osaka City University, Japan, [3]Osaka City University, Japan, [4]Osaka City University, Japan, [5]Kyoto University, Japan

Juvenile hormone III skipped bisepoxide (JHSB3), methyl (2R,3S,10R)-2,3;10,11-bisepoxyfarnesoate was recently determined as a novel juvenile hormone (JH) in the stink bug, Plautia stali. In the previous study, the juvenilizing activity of JHSB3 was tested only in a limited dose range. To further confirm the biological function of JHSB3 in this insect, not only juvenilizing activity in a wider dose range, but also reproduction-stimulating and diapause-terminating activities were examined. Topical application of JHSB3 to last instar nymphs inhibited their metamorphosis in a dose-dependent fashion. In allatectomized and diapausing adults, JHSB3 application exerted stimulatory effects on the development of the ovaries and ectadenia in females and males, respectively. In the previous study the in vitro product of the corpora allata was used as a biological sample, but its presence in the hemolymph has not been examined yet. The present study asked whether JHSB3 was detected from the hemolymph. Gas chromatography-mass spectrometry analysis showed that JHSB3 content in the hemolymph samples from reproductively active females was relatively high while its content in the hemolymph from diapause females was below the detection limit. These results demonstrated that JHSB3 has biological function as a JH in P. stali. Topical application of stereoisomers of JHSB3 and 10R-JH III also indicated that compounds with the 2R,3S-configuration were more potent than those with the 2S,3R-configuration and 2,3-double bond.

Study on microbiota diversity and cellulolytic bacterial community in the hindgut of *Holotrichia parallela* larvae (Coleoptera: Scarabaeidae)

Shengwei Huang[1], Hongyu Zhang[2]

[1]College of Plant Science and Technology, Huazhong Agricutural University, China, [2]College of Plant Science and Technology, Huazhong Agricutural University, China

Gut microbiota has diverse ecological and evolutionary effects on their hosts. However, the ways in which it responds to environmental heterogeneity remain poorly understood. To this end, we surveyed intestinal microbiota of Holotrichia parallela larvae from different geographic regions. Firmicutes and Proteobacteria were the major phyla, and bacteria belonging to Ruminococcaceae, Lachnospiraceae, Enterobacteriaceae, Desulfovibrionaceae and Rhodocyclaceae families were commonly found in all natural populations. However, bacterial diversity (Chao1 and Shannon indices) and community structure varied across host populations, and the observed variation can be explained by soil pH, organic carbon and total nitrogen, and the climate factors (e.g., mean annual temperature) of the locations where the populations were sampled. Our results suggest that the gut's bacterial community changes in response to environmental heterogeneity, possibly to meet the host's ecological needs or physiological demands. Furthermore, to specifically evaluated the nutritional contributions of gut microbiota to scarabs , we isolated and identified cellulose-degrading bacteria from the gut of H. parallela. Our results showed that the cellulolytic bacterial community is dominated by the Proteobacteria (70.05%), followed by the Actinobacteria (24.15%), the Firmicutes (4.35%), and the Bacteroidetes (1.45%). At the genus level, Pseudomonas, Ochrobactrum, Rhizobium, Cellulosimicrobium, and Microbacterium were the predominant groups. However, some bacterial isolates are reported to be cellulolytic for the first time in this study, indicating that the scarab gut is an attractive source for the study of novel cellulolytic microorganisms and enzymes useful for cellulose degradation.

Molecular diversity and function on host of the intestine bacteria of *Bactrocera dorsalis* adults

Hongxiu Wang[1], Hongyu Zhang[2]

[1]College of Plant Science and Technology, Huazhong Agricutural University, China, [2]College of Plant Science and Technology, Huazhong Agricutural University, China

In this paper, the 16S rDNA cloned libraries and DGGE fingerprinting was used to investigate bacterial diversity in the intestinal tract of lab-reared, lab sterile sugar-reared and field-collected populations of Bactrocera dorsalis adult. The results revealed that Gammaproteobacteria was dominant in the all samples (73.0%?98.3%). Actinobacteria and Firmicutes were judged to be major components of a given library since they constituted 10% or more of the total clones of such library. The Flavobacteria, Deltaproteobacteria, Bacteroidetes, and Alphaproteobacteria were observed in small proportions. LIBSHUFF analysis showed that the bacterial communities of B. dorsalis from the three populations were significantly different from each other ($P < 0.0085$). The whole beer、filtered and autoclaved supernatants of fermentation cultures of the cultured gut bacteria had attractiveness to B. dorsalis adults. Autoclaved supernatants were significantly more attractive than the whole beer or filtered supernatants. Six isolates, which autoclaved supernatants were most attractive, were selected to attract to B. dorsalis adults in field. Results showed that LRC38 was more attractive than others. The effect of the dominant Enterobacteriaceae community and the minor Bacillus community on B. dorsalis was assessed. The results showed that feeding on Bacillus had a negative effect on longevity while feeding on the Enterobacteriaceae mixture had a beneficial effect. Compared to flies fed on sugar alone, flies fed on Bacillus died at a significantly faster rate and their average longevity was significantly reduced. Conversely, flies fed on Enterobacteriaceae died more gradually and lived significantly longer.

Comparative analysis of major transcripts from the salivary glands of two insect-feeding hemipteran bugs, *Agriosphodrus dohrni* and Orius strigicollis

Nana Okada[1], Hirotomo Kato[2], Yoko Takematsu[3], Jun Kobayashi[4]

[1]Yamaguchi University, Japan, [2]Hokkaido University, Japan, [3]Yamaguchi University, Japan, [4]Yamaguchi University, Japan

There are a number of hemipteran bugs feeding on insects, and some of them are utilized as biological control agents. Although their saliva must contain specialized enzymes and toxins for feeding their preys effectively, the information on these components is limited. Two insect-feeding bugs, an assassin bug Agriosphodrus Dohrn (Ad, Reduviidae) and a flower bug Orius strigicollis (Os, Anthocoridae), are less related phylogenetically and have distinctive prey preferences (lepidopteran larvae, spiders and millipedes in Ad, and thrips and spider mites in Os, respectively), posing a question whether their saliva components are considerably different or not. To answer this, we have constructed cDNA libraries from their salivary glands and performed comparative analysis on the major transcripts. Randomly selected 470 clones for each library were sequenced and classified into 180 and 169 unique transcripts for Ad and Os, respectively. These transcripts of Ad (Os) were further subdivided into 41 (41) housekeeping gene homologs, 27 (12) digestive enzyme and protease gene homologs, 27 (12) other gene homologs, and 85 (104) transcripts with unknown function (including those with no homolog). Comparison of Ad and Os transcripts revealed that homologs of hemolysin and trialysin-like pore-forming proteins of mammalian blood-sucking bug, Triatoma infestans (Reduviidae), were abundantly transcribed in Ad but not in Os, while a homolog of ADO1 toxin of Ad was identified in Os, suggesting that there are a few conserved salivary proteins among insect-feeding bugs, although the other components varied among species due to phylogenetic constraints.

In vitro assay using cultured insect cells expressing mosquito acetylcholinesterase mutants predicts development of resistance to novel insecticides by single point mutations at a target amino acid

Yu Mukai[1], Hiromu Kawamoto[2], Daijiro Kodama[3], Makoto Itakura[4], Jun KOBAYASHI[5]

[1]Yamaguchi University, Japan, [2]Yamaguchi University, Japan, [3]Yamaguchi University, Japan, [4]Yamaguchi University, Japan, [5]Yamaguchi University, Japan

Acetylcholinesterases (AChEs) play an essential role in neurotransmission at cholinergic sysnapses in animals, and possess a catalytic serine residue, which is a target of organophosphorous and carbamate insecticides. Excess use of these insecticides caused poisoning in humans and other vertebrates, and generated resistant insects. Recently, as effective and safer insecticides, small molecules, which target a cysteine residue found at the AChE active site of many insects but not in mammals, have been proposed (Pang et al., 2009). To predict whether the resistance to the novel insecticides could be developed by single point mutations at the target cysteine residue, we have constructed a series of mutated cDNAs of Culex tritaeniorhychs AChEII, a paralog of Drosophila melanogaster AChE, and their enzymatic activities by transient expression in Ke17 cells derived from Bombyx mori embryos were compared. Although all of the mutants except for a nonsense mutant were produced at quantitatively and qualitatively similar levels with the wild-type AChEII (control), their activities varied and were lower than the control. Among them, three mutants to glycine, phenylalanine and serine residues by single nucleotide substitutions showed activities more than 30% of the control respectively, and the activity of a mutant to leucine by a two-nucleotide substitution was almost comparable to the control. These results by in vitro assay rationalize the prediction that resistance to the novel insecticides targeting the cysteine residue would be developed by single point mutations at the target site immediately after excess use.

The circatidal rhythm of the mangrove cricket persists after removal of the optic lobe.

Hiroki Takekata[1], Sakiko Shiga[2], Hideharu Numata[3]

[1]Osaka City University, Japan, [2]Osaka City University, Japan, [3]Kyoto University, Japan

It has long been controversial whether the circatidal rhythm is a tidally adapted circadian rhythm and generated by a similar mechanism to the circadian clock. The mangrove cricket, Apteronemobius asahinai, inhabits the intertidal zone and synchronizes their activity to tidal flooding and ebbing cycles. Under constant conditions, this cricket shows two rhythms simultaneously in its locomotor activity. One is a circatidal rhythm alternating active and inactive phases and the other is a circadian rhythm modifying the activity intensity in the circatidal active phase. Because these circatidal and circadian rhythms entrain to periodic inundation and light-dark cycles, respectively, the activity rhythm is controlled by two independent clocks. RNA interference of the circadian clock gene period disrupts only the circadian rhythm but not the circatidal rhythm. This fact suggests a difference in molecular mechanisms between the circatidal and circadian clocks. In the present study, we examined the neural mechanisms of these two clocks. The optic lobe was shown to be the locus of the circadian clock in other crickets, but the locus of the circatidal clock is still unknown. To clarify whether the same neurons generate the circatidal and circadian rhythms, we observed the locomotor activity after surgical removal of the optic lobe. After bilateral removal of the optic lobes, most crickets showed the circatidal rhythm, but the circadian rhythm was not observed. In A. asahinai, therefore, the circadian clock is located in the optic lobe as in other crickets, but the circatidal clock exists out of the optic lobe.

Keywords:*circatidal rhythm, Apteronemobius asahinai, optic lobe*

Glutathione S-transferase levels in bed bugs in Thailand

Sonthaya Tiawsirisup[1], Nat Malainual[2], Apiwat Tawatsin[3], Usavadee Thavara[4], Mamoru Watanabe [5]

[1]Faculty of Veterinary Science, Chulalongkorn University, Bangkok, Thailand, [2]Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand, [3]National Institute of Health, Ministry of Public Health, Nonthaburi, Thailand, [4]National Institute of Health, Ministry of Public Health, Nonthaburi, Thailand, [5](4) National Institute of Infectious Diseases, Japan

Bed bug is a blood sucking insect found in several countries including Thailand. Eradication of this insect from household is difficult due to its behavior and insecticide resistance which can be indicated by an increase in such enzymes as acetylcholinesterase, esterase, glutathione S-transferase (GST), and monooxygenase. The current study aims to investigate the GST levels in bed bugs collected from various locations in Thailand by means of a GST Colorimetric Activity Assay Kit. There were 78 samples of Bangkok strain, 49 samples of Chonburi strain, 43 samples of Phuket strain, 19 samples of Krabi strain, and 8 samples of Chiangmai strain of Cimex hemipterus and 21 samples of Chiangmai strain of Cimex lectularius. There were two subgroups of Bangkok strain: 37 samples of non-insecticide exposed and 41 samples of insecticide exposed bed bugs. The average GST levels were 0.071 and 0.019 µmol/min/mg protein for non-insecticide exposed and insecticide exposed subgroup, respectively. The average GST levels were 0.011, 0.024, 0.017, and 0.010 µmol/min/mg protein for Chonburi, Phuket, Krabi, and Chiangmai strain of Cimex hemipterus, respectively. The average GST level of Chiangmai strain of Cimex lectularius was 0.007 µmol/min/mg protein. In addition, GST levels of insecticide resistance Chiba (Japan) and insecticide susceptible Tokyo (Japan) strain of Cimex lectularius were tested. The average GST levels were 0.018 and 0.030 µmol/min/mg protein for Chiba and Tokyo strain of Cimex lectularius, respectively. These data revealed that GST level should not be used as a single indicator of insecticide resistance status in bed bugs in Thailand.

Role of yeast-like endosymbiotes (YLS) of brown planthopper, *Nilaparvata lugens* (Stal) in the development of resistance its host to imidacloprid, neonicotinoid insecticide

Juefeng Zhang[1], Na Li[2], Yueping He[3], Jianming Chen[4]

[1]Zhejiang Academy of Agricultural Science, China, [2]Zhejiang Academy of Agricultural Science, China, [3]Zhejiang Academy of Agricultural Science, China, [4]Zhejiang Academy of Agricultural Science, China

The brown planthopper (BPH), Nilaparvata lugens, is one of major insect pests of rice production in Asian county. In China, chemical control is still main way for suppressing BPH populations, one of main causes of BPH frequency-outbreak is high resistance of BPH to imidacloprid, neonicotinoid insecticide. So delay and management of BPH resistance to the insecticide will be an urgent and important topic to be solved in rice production. The experiment found some differences in population diversity of YLS in imidacloprid-resistant and -susceptible BPH populations. In which, resistant and susceptible BPH had four and three kinds YLS, respectively. YLS numbers was related to its host activities of detoxification enzymes and resistance level. Activities of carboxylesterase (CarE), mixed function oxidase (MFO), superoxide dismutase (SOD), peroxidase (POD), uricase and lipase in imidacloprid-resistant YLS strain were significantly higher than those in imidacloprid-susceptible strain, while activity of glutathione-s-transferase (GST), catalase (CAT) had no obvious difference between two resistant strains. Under 24-32℃ temperature, the normal degradation half-life of imidacloprid at concentration of 10 mg/L was 48.8-61.3d, the half-life of imidacloprid-susceptible and resistant strains to imidacloprid was 43.6-60.3d and 32.0-39.4d, respectively. This indicated imidacloprid-susceptible strains had no degradation ability, and imidacloprid-resistant strains had some degradation capacity. We further found that temperature of environment, concentration of imidacloprid, resistant level of strains affected significantly degradation capacity of symbiotic strain to imidacloprid. One gene relative with imidacloprid-detoxification in YLS was cloned. Those results will provide the theoretical foundation for reasonable explanation of resistant mechanism of BPH to neonicotinoid.

Involvement of a circadian system in the circannual rhythm in the varied carpet beetle *Anthrenus verbasci*

Yosuke MIyazaki[1], Tomoyosi Nisimura[2], Tomoya Matsuno[3], Hideharu Numata[4]

[1]Ashiya University, Japan, [2]Nihon University, Japan, [3]Osaka City University, Japan, [4]Kyoto University, Japan

The varied carpet beetle, Anthrenus verbasci, regulates the timing of pupation by a circannual rhythm. The circadian clock controls various physiological functions in most organisms, but its involvement in circannual rhythms has been controversial. We examined whether a circadian system is involved in the circannual rhythm in A. verbasci. Larval duration under light-dark cycles of 20-26 h was not proportional to the period of the cycles (T). Moreover, there was no significant correlation between the pupation time and the circadian period in adult locomotor activity under constant light. Entrainment of this circannual rhythm to annual cycles is achieved by phase resetting in response to photoperiodic changes. To examine whether a circadian system is involved in the phase resetting of the circannual rhythm, we exposed larvae to light-dark cycles with a short photophase followed by a variable scotophase (the Nanda-Hamner protocol). When T was a multiple of 24 h, i.e., 24, 48, or 72 h, short-day effects were clearer than when T was far from a multiple of 24 h, i.e., 36 or 60 h. Exposure to light-dark cycles of T = 36 h had effects similar to those by exposure to long-day cycles of T = 24 h. We conclude, therefore, that the mechanism generating the circannual rhythm is independent of the circadian clock but a circadian system is involved in photoperiodic time measurement for phase resetting in the circannual rhythm of A. verbasci.

GST underlying the rhythmic resistance against permethrin in the German cockroach

Yu-Hsien Lin[1], Jia- Hsin Huang[2], Yun Liu[3], How-Jing Lee[4]

[1]National Taiwan University, Taipei, Taiwan, [2]National Taiwan University, Taipei, Taiwan, [3]National Taiwan University, Taipei, Taiwan, [4]National Taiwan University, Taipei, Taiwan

Even though numerous studies have confirmed the daily variation of susceptibility to xenobiotic compounds in animals, there are a few reports studying molecular mechanisms underlying the daily rhythm of insecticide resistance in insects. In the present study, we investigated the daily susceptibility rhythm to permethrin and the expression level of the delta class glutathione S-transferase (BgGSTD1) gene in Blattella germanica. Male cockroaches were exposed to the same concentration of permethrin at different time points in a light-dark cycle, and results showed that the highest resistance occurred during night time. Furthermore, the circadian control of permethrin resistance can be demonstrated by the fact that the highest resistance took place at subjective night under constant darkness. The mRNA expression of the BgGSTD1 gene in the fat body of B. germanica peaked in the early day time, whereas the enzyme activity of cytosolic GSTs showed no daily fluctuations. RNA interference (RNAi) was employed to study the role of BgGSTD1 in the circadian rhythm of permethrin resistance in B. germanica. Both BgGSTD1 mRNA level and cytosolic GSTs activity were significantly decreased by RNAi. Notably, the RNAi-mediated silencing effect appeared to cause greater reductions in the cytosolic GSTs enzyme activity at night than in the day time. In addition, the survival rates of B. germanica with silenced BgGSTD1 were significantly decreased at night but not in the day time when the cockroaches were exposed to permethrin. These results have demonstrated that BgGSTD1 plays an important role in circadian control of permethrin resistance in B. germanica.

DNA methylation during the caste determination in the European honeybees, Apis mellifera

Hironori Sakamoto[1], Miho Suzuki[2], Shinnosuke Ishii[3], Tetsuhiko Sasaki[4]

[1]Tamagawa University, Japan, [2]National Institute for Basic Biology, Japan, [3]Tamagawa University, Japan, [4]Tamagawa University, Japan

Differentiation between queen and worker in honeybees is determined by larval nutrition intake. Female larvae up to 3 days after hatching can grow into either queen or worker, and the fate of larva is irreversibly-determined on the 4th day after hatching. To clarify the epigenetic control of caste determination, genome-wide DNA methylation pattern were compared between queens and workers on the 4th day after hatching by next generation sequencing technology. We identified 1,717 CpG sites that showed significant difference in methylation frequency between queens and workers. Interestingly, transformer-2 (tra-2), a sex-determining gene, contained three differently methylated CpG sites. This observation implied that tra-2 is involved in caste differentiation as well as in sex determination. To further examine this possibility, we investigated the methylation pattern of tra-2 in 3- to 5-day old workers and queens by bisulfite sequencing. We report two main results: (1) methylation pattern in larvae drastically changes during developmental stage in both workers and queens, (2) the patterns of the changing are greatly different between castes.

Identification of sex pheromone components in *Trissolcus brochymenae* females

Gianandrea Salerno[1], Gianfranco Anfora[2], Alessia Iacovone[3], Francesca Frati[4], Eric Conti[5]

[1]University of Perugia, Italy, [2]Research and Innovation Centre, Fondazione Edmund Mach, Italy, [3]University of Perugia, Italy, [4]University of Perugia, Italy, [5]University of Perugia, Italy

Long- and short-range sex pheromones appear to play a crucial role in the mate finding and courtship behavior of most parasitic Hymenoptera. Yet these parasitoids have been rarely investigated and only a few pheromones have been identified. Recent studies have shown that sexual communication in Trissolcus brochymenae (Hymenoptera: Platygastridae), a quasi-gregarious egg parasitoid of the harlequin bug, Murgantia histrionica (Heteroptera: Pentatomidae), starts before contact between males and females and is mediated by chemical compounds produced by virgin females, which triggers the courtship behavior in males. In this study, the pheromone components involved in the short-range recognition of T. brochymenae females by males were investigated using electrophysiological and behavioral methods. Female body extracts were analyzed through EAG and GC-EAD and the active compounds were identified through GC-MS. Then the behavioural responses of virgin males to the GC-EAD active compounds were evaluated in closed arena bioassays. Two electrophysiologically and behaviorally active compounds were identified as sex pheromone components, tetradecyl acetate and (Z)-11-hexadecen-1-yl acetate. Both compounds triggered intense male antennation and mounting when applied on solvent washed female cadavers. Dose-response tests showed different curves for the two compounds. This is the first study on the identification of sexual pheromones in Platygastridae. The difficulties of sex pheromone investigations on such minute egg parasitoids and the possible exploitation of these new findings in IPM are discussed.

The neuropeptide allatostatin A and its receptor DAR-2 regulate metabolism in *Drosophila*

Julie L. Hentze[1], Mikael A. Carlsson[2], Ole Andersen[3], Dick R. Nassel[4], Kim F. Rewitz[5]

[1]Roskilde University, Denmark, [2]Stockholm University, Sweden, [3]Roskilde University, Denmark, [4]Stockholm University, Sweden, [5]Roskilde University, Denmark

Knowledge about the neuroendocrine circuits controlling metabolism is important in the struggle to overcome the challenges of diabetes and cardiovascular diseases, and other health problems related to metabolism and food intake. Several elements of metabolic homeostasis are conserved from flies to mammals. The fruit fly Drosophila melanogaster is a powerful genetically tractable model-organism. We are studying a conserved neuroendocrine circuit involving hormones related to glucagon and insulin in mammals, to identify the components and understand their role in the regulation of metabolism. We assume that a key upstream regulator of the circuit is the neuropeptide Allatostatin A (AstA), known to influence feeding behavior. Our data indicate that one of the AstA receptors DAR2 is expressed in three sets of peptidergic neurons, the insulin-producing cells (IPCs), in the adipokinetic hormone (AKH) producing cells of the corpus cardiacum (CC) and in the Corazonin (CRZ)-producing neurons. These hormones are involved in the maintenance of sugar homeostasis and regulation of triglyceride deposits. The AstA neurons directly contact both the CRZ neurons and the IPCs. Furthermore, starvation assays and expression patterns of key metabolic genes, following RNAi mediated knock down of AlstR2 in the CC and IPCs, indicate that AstA is involved in the regulation of AKH, and in insulin release. Taken together, the results indicate that AstA is a regulator of AKH, CRZ and Insulin and that this neuroendocrine system might coordinate feeding and metabolism.

Investigation of lectins as competitors of virus in aphids and potentiality in viral disease transmission

Emilie Bosquee[1], Jeremy Hoste[2], Eric Haubruge[3], Sophie Vandermoten[4], Frederic Francis[5]

[1]University of Liege - Gembloux Agro-Bio Tech, Belgium, [2]University of Liege - Gembloux Agro-Bio Tech, Belgium, [3]University of Liege - Gembloux Agro-Bio Tech, Belgium, [4]University of Liege - Gembloux Agro-Bio Tech, Belgium, [5]University of Liege - Gembloux Agro-Bio Tech, Belgium

Awareness of the danger of the excessive use of pesticides to human health and the environment has led to some scientific research to develop alternative strategies for pest management. All these investigations aim to reduce the massive use of toxic chemicals. In order to have efficient control of viral diseases by reducing the aphid vector dispersion virus transmission efficiency, some interesting glycoproteins such as lectins were found to be potential competitors to virus. Indeed, these proteins present large affinity to receptors located from the sucking mouth parts to the hindgut of the vectory aphids. In this study, the effects of three lectins on the transmission of three non-persistant viruses were tested in laboratory on Myzus persicae via the use of artificial diets. The glycoproteins used were Canavalia ensiformis agglutinin (ConA), Galanthus nivalis agglutinin (GNA) and wheat germ agglutinin (WGA) and the viruses studied were PVY (Potato virus Y), CMV (Cucumber Mosaic Virus) and TuMV (Turnip Mosaic Virus). An interference between GNA and all viruses was observed. In addition, a competition between WGA and two viruses i.e. CMV and TuMV was highlighted. In consequence, the two latter lectins were considered as promising proteins to reduce the transmission of these viruses. Strategies based on pre-feeding aphids with lectins before potential virus transmission and application in fields were discussed in terms of sustainable and efficient reduction of viral disease in crops.

Effect of reduced water supply on aphid physiology : a proteomic approach on peach-aphid interaction

Jaime A. Verdugo[1], Jean-Philippe Lacroze[2], Marie-Helene Sauge[3], Sophie Vandermoten[4], Ramirez C. Claudio[5], Frederic Francis[6]

[1]University of Liege - Gembloux Agro-Bio Tech, Belgium, [2]INRA, France, [3]INRA, France, [4]University of Liege - Gembloux Agro-Bio Tech, Belgium, [5]Universidad de Talca, Chile, [6]University of Liege - Gembloux Agro-Bio Tech, Belgium

Whether the effect of water lacking was mainly studied on plant responses, very few investigations were developped on the herbivore responses to water deficiency in host plant. Here, a proteomic approach related to clones of the green peach aphid Myzus persicae which was exposed to normal and water deficient irrigation was studied. After 48 hours, as compared to aphids fed on control plants (well-watered), the aphids fed under water-deficit exhibited several proteins up-regulated. Most of the proteins exhibiting changes were involved in energy metabolism (as Regulator of G-protein signaling 7-like and RNA 3' terminal phosphate cyclase), or were associated to cytoskeleton functionality (as actin related protein 1 and F-actin capping protein subunit beta). One of these proteins was significantly down-regulated, the mitochondrial-processing peptidase, which is associated with aphid response to toxicity. Moreover, some proteins from the Buchenra aphidicola were found to be deregulated. Presence of only primary symbiont was assessed by PCR approach. In a parallel experiment using similar treatments as in the proteomic study, the population rate of growth (PGR) of aphids were determined. These findings suggested that plant under water deficit suffers of physiological changes which in turn elicit (or "transferred to") a significant proteomic changes on aphids fed on them.

Termites artificially-fed on unusual diet and resulting enzymatic switches

Julien Bauwens[1], Cedric Tarayre[2], Christel Matteotti[3], Chaterine Brasseur[4], Jacqueline Destain[5], Micheline Vandenbol[6], Daniel Portetelle[7], Philippe Thonart[8], Edwin De Pauw[9], Sophie Vandermoten[10], Eric Haubruge[11], Frederic Francis[12]

[1]University of Liege - Gembloux Agro-Bio Tech, Belgium, [2]University of Liege - Gembloux Agro-Bio Tech, Belgium, [3]University of Liege - Gembloux Agro-Bio Tech, Belgium, [4]University of Liege, Belgium, [5]University of Liege - Gembloux Agro-Bio Tech, Belgium, [6]University of Liege - Gembloux Agro-Bio Tech, Belgium, [7]University of Liege - Gembloux Agro-Bio Tech, Belgium, [8]University of Liege - Gembloux Agro-Bio Tech, Belgium, [9]University of Liege, Belgium, [10]University of Liege - Gembloux Agro-Bio Tech, Belgium, [11]University of Liege - Gembloux Agro-Bio Tech, Belgium, [12]University of Liege - Gembloux Agro-Bio Tech, Belgium

Wood-feeding termites as Reticulitermes santonensis generally feed on cellulose, hemicelluloses and lignin. However, these opportunistic insects are also able to degrade other carbohydrates, such as starch. The production of putative endogenous α -amylase has been previously shown in R. flavipes, as the disappearance of the major symbiotic flagellates from the hindgut. Here, we compared enzymatic activities (CMCase, MCCase, xylanase, amylase, α- and β-glucosidase) between different fractions of the digestive tract of starch-, cellulose-, and wood-fed termites. Main compounds of the artificial diets, namely starch or MCC, resulted in differential enzymatic activity. Even the substitution of wood by artificial diets itself seemed to induce changes in enzymatic activities, regardless of the main substrate in the diet, as we observed strong midgut α-glucosidase activity only for artificially-fed termites. Preliminary assays to isolate and characterize enzymes were performed using proteomic methods.

Cloning and expression of a membrane form guanylyl cyclase, BdmGC-2, in the oriental fruit fly, *Bactrocera dorsalis*

Jen-Dau Liu[1], Jer-cherng Chang[2], Ruey-Bing Yang[3], Kuang-Hui Lu[4]

[1]National Chung Hsing University, Taiwan, [2]National Chung Hsing University, Taiwan, [3]Academia Sinica, Taiwan, [4]National Chung Hsing University, Taiwan

Guanylyl cyclases (GCs), an important group of enzymes, catalyze formation of cGMP for intracellular signal transduction in both mammals and insects. In our current study, a cDNA of membrane form GC has been isolated from the oriental fruit fly, Bactrocera dorsalis (Hendel), designed BdmGC-2. The BdmGC-2 cDNA, with size of 5,750 bp, contains a 4,524-nucleotide open reading frame encoding a protein of 1,508 amino acids. BdmGC-2 contains four functional domains, i.e. extracellular ligand binding domain, transmembrane domain, kinase-like domain and cyclase catalytic domain, which is similar to all known receptor GCs. BdmGC-2 was expressed in all developmental stages of B. dorsalis. Real-time PCR assay revealed that during the pupal development BdmGC-2 expression was gradually reduced in the early stages, yet it was increased again after six days. Furthermore, BdmGC-2 was constitutively expressed in the various tissues of both male and female adults, mainly in the brain, testis and Malpighian tubules. Among them, the Malpighian tubules have the highest amount of BdmGC-2 expression; moreover, whole-mount in situ hybridization has further confirmed the expression of BdmGC-2 in the Malpighian tubules.

Hemolymph melanization in the silkmoth *Bombyx mori* requires the formation of a high molecular mass complex that metabolizes tyrosine

Kevin D. Clark[1], Michael R. Strand[2]

[1]*University of Georgia, U.S.A.*, [2]*University of Georgia, U.S.A.*

A key immune response exhibited by arthropods is the melanization of hemolymph. The enzyme phenoloxidase (PO) is thought to assume the same metabolic role in melanin formation as a class of enzymes called tyrosinases, which oxidize tyrosine (Tyr) and o-diphenols to their corresponding quinones. However, purified POs only poorly metabolize Tyr, and the actual melanization substrate has not been unequivocally identified. We have found that, unlike purified PO, Tyr is rapidly converted to melanin in substrate-free plasma (SFP) from B. mori larvae. HPLC separations of B. mori plasma showed only a single fraction containing a melanin-producing substrate, which was identified as Tyr. Tyr rapidly disappeared in melanizing B. mori plasma, while phenylthiourea, an inhibitor of melanization, blocked its metabolism. To determine what was utilizing tyrosine, plasma from B. mori was separated by gel filtration chromatography. Tyr-dependent melanizing activity was observed only in a high mass (670kD) melanization complex (MC) significantly larger than PO. However, PO was essential for activity: (1) Egf1.0, a viral inhibitor of pro-PO processing, blocked the formation of the MC. (2) Immunoblots using a B. mori-specific PO antibody showed the formation of a high mass MC. (3) Trypsin digestion and mass spectrometry of the MC indicated the presence of PO. Overall, our finding that the substrate for melanin formation is Tyr and that it is metabolized solely by a PO-containing high mass MC undermines the long-held concept that PO activation alone is sufficient for melanization.

Effects of temperature and photoperiod on hypermetamorphosis in the been blister beetle, *Epicauta gorhami*

Yoshinori Shintani[1], Misato Terao[2], Yuzuru Hirose[3]

[1]Minami Kyushu University, Japan, [2]Minami Kyushu University, Japan, [3]Minami Kyushu University, Japan

Larvae of the bean blister beetle, Epicauta gorhami (Coleoptera: Meloidae), feed on grasshopper eggs in soil and undergo hypermetamorphosis. This beetle has larval diapause in the 5th instar as a pseudopupa, a form characteristic of hypermetamorphosis in meloid beetles. Effects of temperature and photoperiod on larval development of E. gorhami were examined in a population in Miyazaki, Japan. At 20 and 22.5ºC, all larvae became pseudopupae in the 5th instar, regardless of the photoperiod. In contrast, at 27.5 and 30ºC, almost all larvae pupated from the 4th instar, again regardless of the photoperiod. A long-day photoperiodic response occurred only at 25ºC: under 12L-12D, all larvae entered diapause, but the diapause incidence tended to decrease as the day length became longer. Pseudopupae were immobile and remained in diapause for a long period. Based on the short developmental period and diapause avoidance under summer conditions, it was suggested that this beetle partially produces two generations a year in southwestern Japan. Pseudopupal diapause was terminated by exposure to low or high temperature. The optimum low temperature for diapause termination was 10-15ºC. There was an individual variation in the low temperature requirement for diapause termination and post-diapause development may not occur until this requirement is satisfied. Although under natural conditions pseudopupae may encounter low temperatures that are effective for diapause termination at different ages, our results show that pseudopupae at various ages respond similarly to low temperature exposure. This response may ensure that resumption of development synchronizes in a population.

Larval development and diapause in the ramie longicorn beetle, *Paraglenea fortunei*

Ryohei Miyahara[1], Jun-ya Tajima[2], Yoshinori Shintani[3]

[1]Minami Kyushu University, Japan, [2]Minami Kyushu University, Japan, [3]Minami Kyushu University, Japan

The ramie longicorn beetle, Paraglenea fortunei (Coleoptera: Cerambycidae), feeds on weeds such as the ramie, Boeheria nivea, and trees such as the cotton rosemallow, Hibiscus mutabilis, in both the larval and adult stages. This beetle overwinters in the larval stage and emerges and reproduces in early summer. To examine seasonal adaptations of P. fortunei, effects of temperature (20, 25 and 30ºC) and photoperiod (12L-12D, 14L-10D and 16L-8D) on larval development were examined by rearing larvae after hatching using artificial diets in a local population in Miyazaki, Japan. Artificial diets used were Silkmate 2S, Insecta LFM, and Insecta F-II with dried leaf powder of the ramie (each commercial diet was from Nihon Nosan Co.). Body weight of the larvae varied with dietary conditions, but developmental profiles did not vary significantly among the conditions. The higher the temperature, the more times larvae underwent molts (mostly 3-6 times), but irrespective of the temperature and photoperiod, most larvae ceased feeding and did not pupate under constant conditions, except for the larvae that pupated precociously. When the larvae reared at 25ºC were exposed to lower temperatures (12.5 and 15ºC) for 30-60 days, a part of them pupated after return to 25ºC. These results indicate that this beetle has obligatory larval diapause that is terminated by low temperatures and thereby retains univoltine life cycles in the field.

How are odorant binding proteins involved in olfaction of *Tribolium castaneum?*

Karthi Murugan[1], Stefan Dippel[2], Sergio Angeli[3], Paolo Pelosi[4], Jochen Schachtner[5], Ernst Wimmer[6], Stefan Schutz[7]

[1]University Gottingen, Germany, [2]University Gottingen, Germany, [3]University of Bolzano, [4]Agricultural University Pisa, Italy, [5]University Marburg, Germany, [6]University Gottingen, Germany, [7]University Gottingen, Germany

The red flour beetle (Tribolium castaneum) is accessible to transgenic approaches as directed gene expression, powerful reverse genetics based on systemic RNA interference and a recently published full genome sequence. Moreover, its longevity offers a suitable system to address olfaction from the odor recognition and discrimination at the periphery to the analysis of the plasticity of the central olfactory pathway. According to genome annotation T. castaneum has got 47 odorant binding proteins (OBP) and 19 structurally related chemosensory proteins (CSP). Reverse genetic, electrophysiological and chemo-ecological approaches are combined to study the correlation of odorants to odorant binding proteins (OBP). The biological function of OBPs is still largely unknown, despite their necessity for olfaction. Especially the interaction of OBPs with odors is of key interest and is evaluated at the molecular and at the electrophysiological level.

Rising CO2 associated with climate change may affect the interactions between plants, pathogens and their vectors. Although plant response to elevated CO2 (eCO2) has been well studied, little is understood about the interactions between plants, insects and pathogens under simulated future climates. Subsequently, there is a lack of knowledge on how the plant and vector metabolome will respond to future atmospheric changes. Controlled environment growth chambers are being used to study the effect of eCO2 on this complex system. Experiments so far have examined the change in the metabolome of aerial wheat tissue due to infection by Barley yellow dwarf virus (BYDV) as transmitted by the aphid Rhopalosiphum padi under atmospheric CO2 and eCO2 (650ppm). Metabolomic analysis by LCMS profiling will be presented. Preliminary analysis reveals strong metabolic shift between control and virus infected plants with a more moderate effect due to eCO2.

Juvenile hormone biosynthetic organs in the final larval instar of the red flour beetle *Tribolium castaneum*.

Fumika Ishii[1], Ken Miura[2], Toshiharu Tanaka[3], Chieka Minakuchi[4]

[1]Nagoya university, Japan, [2]Nagoya university, Japan, [3]Nagoya university, Japan, [4]Nagoya university, Japan

Juvenile hormone acid O-methyltransferase (JHAMT) is an enzyme working in the final step of juvenile hormone (JH) biosynthesis. In Tribolium castaneum, RNA interference-mediated knockdown of JHAMT resulted in precocious larval?pupal metamorphosis due to precocious shutdown of JH biosynthesis. Generally, JHAMT is specifically expressed in the corpora allata, while existence of JHAMT mRNA in ovary and testis has been reported in the final larval instar in several insect species. It was found that JHAMT mRNA is expressed in the thorax or abdomen of last instar of T. castaneum (Minakuchi et al., 2008), but the tissue in which JHAMT mRNA exists has not yet been identified. In this study, temporal and spatial expression of JHAMT mRNA in the final larval instar was examined using quantitative RT-PCR. The amount of JHAMT mRNA in thorax-abdomen part was low until Day 3 of the final larval instar, and high in the prepupal stage. Further, the amount of JHAMT transcript in the thorax-abdomen of wandering larvae was relatively similar to the head containing the corpora allata. To identify the segments in which JHAMT is expressed, the thorax-abdomen was cut into anterior and posterior parts, then JHAMT mRNA was quantified. Although the JHAMT transcript level was relatively high in the posterior part of thorax-abdomen, it seemed that JHAMT was broadly expressed in thorax and abdomen. Further studies including in situ hybridization are in progress.

Insect hormones regulate the expression of diapause hormone receptor gene of the silkworm (*Bombyx mori*) In Vitro

Xingjia Shen[1], Ligang Wang[2], Shunming Tang[3], Shengpeng Wang[4], Qiaoling Zhao[5]

[1]Jiangsu University of Science and Technology, China, [2]Jiangsu University of Science and Technology, China, [3]Jiangsu University of Science and Technology, China, [4]Jiangsu University of Science and Technology, China, [5]Jiangsu University of Science and Technology, China

In the process of silkworm (Bombyx mori) diapause, the diapause hormone receptor (BmDHR) plays important roles. To study the regulation mechanism of BmDHR, two heterogeneous promoter fragments of Bmdhr were cloned into pGL3.0 basic vector to construct reporter plasmids, respectively. And the effects of foreign insect hormones including juvenile hormone analogue (JHA), 20-OH-ecdysone and diapause hormone (DH) on regulation of Bmdhr promoter activities were analyzed in BmN cells. The results showed that the activity of 1395 bp promoter fragment was significantly lower than that of 972 bp one, implying that there is a negative regulation element between -941 and -1364 nt of Bmdhr promoter region. JHA of 2, 4 and 6 μg/mL increased the promoter activity by 1.5-2.1 folds. The effects of 20-OH-ecdysone on Bmdhr promoter activity revealed a dosage dependent profile, low concentration 20-OH-ecdysone (1, 2 μg/mL) increased the promoter activity significantly, 20-OH-ecdysone of 4μg/mL strongly suppressed the promoter activity. When 20-OH-ecdysone concentration increased to 8 and 10 μg/mL, the promoter activity recovered and increased significantly again. Mixture of 1 μg/mL JHA and 20-OH-ecdysone increased the Bmdhr promoter activity by 1.6 folds to the peak. With the increase of mixture concentration the Bmdhr promoter activity decreased gradually, and high concentration (8 and 10 μg/mL) of mixture decreased the promoter activity. The effects of DH revealed a dosage dependent profile too, low concentration DH (10, 20 and 40 nmol?L-1) significantly enhanced the promoter activity, but high concentration DH (60 to 100 nmol?L-1) showed no significant effect.

Nutrition and radiation influence protein expression on oriental fruit fly pupae

Chiou Ling Chang[1], Scott Geib[2], Thomas A. Coudron[3], Cynthia L. Goodman[4], David Stanley[5]
[1]USDA, U.S.A., [2]USDA, U.S.A., [3]USDA, U.S.A., [4]USDA, U.S.A., [5]USDA, U.S.A.

Background: We reported on a study designed to identify molecular markers of deficiencies in culture media developed for the oriental fruit fly. In that study, we found significant changes in expression of 70 proteins in adults of larvae reared on media lacking wheat germ oil (WGO), compared to media supplemented with WGO and the WGO effect is highest at day 8 (females begin reproductive maturation). In a consecutive papers we addressed the idea that the whole animal proteome changes dynamically with different stages and ages (0-12 d). Methods: We reared separate groups of fruit fly larvae on media with and without WGO supplementation and the one with WGO was treated with different doses of radiations and analyzed protein expression in pupal age 0-11a days old using 2D electrophoresis. Results and discussion: Gel densitometry revealed significant increases (by > 2-fold) and decreases (by > 50%) in expression levels between 2-18 proteins from 1 to 11-d-old pupae respectively between the pupae of larvae reared on + and -WGO and between the pupae of larvae under radiation (IRR) and non-radiation (NIRR) treatment. Three major proteins, bnb (27-fold), nattlectin precursor (13.22 fold), and insect cuticle protein (12.90-fold) increased in expression in day 4, 6, 7 pupae were identified between +/-WGO. Conclusion: The key finding is that both nutrition deficiency and radiation treatment affect changes in protein expression started at day 4 pupae and these changes mainly occurred on developmental protein complex (bnb) located at molecular weight between 25-100 daltons and PI 4.5-5.

Effect of plant secondary compounds on detoxification enzymes and oxidoreductases of cereal aphid

Tingting Fang[1], Guilin Pu[2], Xiaoqin Sun[3], Qingnian Cai[4]

[1]China Agricultural University, China, [2]China Agricultural University, China, [3]China Agricultural University, China, [4]China Agricultural University, China

Plant secondary metabolites have been documented to be deleterious to insects and other herbivores in diverse ways. In this paper, the effect of catechol (phenolics), gramine (alkaloid) and L-ornithine-HCl (non-protein amino acid) on the activities of detoxifying enzymes and oxidoreductases in Sitobion avenae was evaluated. Glutathione S-transferase (GST) and esterase (EST) activities in aphids were significantly or very significantly correlated with each compound concentration in artificial diets. Both two enzyme activities in aphids were significantly activated by gramine in comparison with catechol and L-ornithine-HCl, Peroxidase (POD) and polyphenol oxidase (PPO) activities in aphids were significantly correlated with Catechol and gramine concentrations in the diets, respectively, whereas catalase (CAT) activity in aphids was significantly suppressed by higher concentrations of catechol, gramine and L-ornithine-HCl. Those results indicated that EST and GST were important detoxification enzymes of aphids against plant secondary compounds, and suggested that POD and PPO could involved in aphid defense against phenolics and alkaloids, respectively, whereas three compounds could be inhibitors of CAT acitivity of aphids.

Induction of gene silencing in cultured insect cells by *piggyBac* transposon

Jun Kobayashi[1], Hiroshi Mitsutake[2]

[1]Yamaguchi University, Japan, [2]Yamaguchi University, Japan

The piggyBac transposition system has been widely used for generating various transgenic insects and stably transformed insect cell lines for studying genetic mechanisms and developing new technologies for pest control as well as protein production. Due to a relatively random fashion of piggyBac integration into the genome, its insertion site and copy number among transformants considerably vary, resulting in significant differences in expression level of transgene. In fact, we have established several transgenic clonal lines with different levels of GFP marker gene expression including a few lines with no detectable expression by the piggyBac-mediated transformation of a silkworm cell line BmN4, which was derived from the ovary of Bombyx mori. Analyses of some GFP-negative lines have revealed that, from an endogenous PIWI-interacting RNA (piRNA) cluster (torimochi) of the B. mori genome, an antisense GFP sequence fused with a part of the cluster is commonly transcribed and serves as a source of de novo piRNAs capable of silencing GFP expression in trans (Kawaoka et al., 2012). The results indicate that the piggyBac can be used not only for gene expression but also for gene silencing by the piRNA pathway in BmN4 cells. We are further exploring the efficiency of endogenous gene silencing by the newly found piRNA-generating mechanism.

Electroantennogram and field resoponses of the rice leaf folder, *Cnaphalocrocis medinalis*, to sex attractant candidates in Korea

Jum Rae Cho[1], Jin Kyo Jung[2], Kyung San Choi[3], Hong Hyun Park[4], Bo Yoon Seo[5], Ki Hong Yum[6]

[1]National Academy of Agricultural Science, RDA, Republic of Korea, [2]National Institute of Crop Science, RDA, Republic of Korea, [3]National Institute of Horticultural & Herbal Science, RDA, Republic of Korea, [4]National Academy of Agricultural Science, RDA, Republic of Korea, [5]National Institute of Crop Science, RDA, Republic of Korea, [6]Greenagrotech, Republic of Korea

A series of studies was conducted to find out the optimum sex attractant for monitoring the rice leaf folder, Cnaphalocrocis medinalis, in Korea, based on the previously reported pheromone composition in this species. (Z)-13-Octadecenal (Z13-18:Al) was most active in electroantennogram (EAG) and field tests. (Z)-11-Hexadecenal (Z11-16:Al), (Z)-11-octadecenal (Z11-18:Al), (Z)-11-hexadecenyl acetate (Z11-16:Ac), (Z)-13-octadecenyl acetate (Z13-18:Ac) and (Z)-13-octadecenol (Z13-18:OH) individually elicited significant EAG responses, but the compounds were not attractive individually in fields. (Z)-11-Octadecenol (Z11-18:OH) alone was inactive in both EAG and field tests. The addition of Z11-18:OH and Z13-18:OH to the binary mixture of Z11-18:Al and Z13-18:Al, as the previously reported composition of Japanese blend increased significantly the trap catches of males in fields. In contrast, Philippine and Indian blends were not attractive to this species. Interestingly, when Z13-18:Ac alone was added to the binary mixture of Z11-18:Al and Z13-18:Al, the trap catch number was the same as that of Japanese blend. The present study indicates that the four-component blend (Z11-18:Al/Z13-18:Al/ Z11-18:OH/Z13-18:OH = 11/100/24/36) and the three-component blend (Z11-18:Al/Z13-18:Al/ Z13-18:Ac = 11/100/11) can be used as sex attractants for monitoring the Korean populations of C. medinalis.

Suppression of pheromone biosynthesis via RNA interference in *Plutella xylostella*

Dae-Weon Lee
KyungSung University, Republic of Korea

Sex pheromone production is regulated by pheromone biosynthesis-activating neuropeptide (PBAN) in many lepidopteran species. A cDNA isolated from female adult heads of Plutella xylostella encodes 193 amino acids including PBAN, designated as Plx-PBAN. When female adults were injected with synthetic Plx-PBAN, pheromone production showed a maximal increase 1h post-injection. RT-PCR screening revealed that Plx-PBAN cDNA was expressed in all examined body parts, with the highest expression level in the head of female adults. The PBAN receptor (Plx-PBANr) gene was also cloned from the female pheromone gland. The expression of Plx-PBANr was found only in the pheromone gland of female adults among examined tissues and developmental stages. Heterologous expression in human uterus cervical cancer cells revealed that Plx-PBANr induced significant calcium elevation when challenged with Plx-PBAN. Female P. xylostella injected with double-stranded RNA specific to Plx-PBANr showed suppression of the receptor gene expression and exhibited significant reduction in pheromone biosynthesis, which resulted in loss of male attractiveness. In addition, to assess molecular events occurring downstream of PBAN signaling, partial sequences of Δ9 and Δ11 fatty acid desaturases of P. xylostella. were cloned. Phylogenetic analysis indicated that these two desaturase genes were highly clustered with other desaturases associated with sex pheromone biosynthesis in other insects. RT-PCR analysis showed that Δ9 desaturase was dominantly expressed in adult females, whereas Δ11 desaturase was expressed in all developmental stages. When PBANr expression was suppressed by PBANr-RNAi, the treated females also showed significant suppression of expression of both desaturases.

Identification of *Monochamus alternates* and *M.saltuarius*, the vectors of pimewood nematode, *Bursaphelenchus xylophilus* using internal transcribed spacer fragment in Korea.

Jin ah Hong[1], Chan sik Jung[2], Yil Sung Moon[3], Chul Su Kim[4]

[1]Korea Forest Research Institute, Republic of Korea, [2]Division of Forest Insect Pests and Diseases, Korea Forest Research Institute, Republic of Korea, [3]Division of Forest Insect Pests and Diseases, Korea Forest Research Institute, Republic of Korea, [4]Division of Forest Insect Pests and Diseases, Korea Forest Research Institute, Republic of Korea

Monochamus alternatus(MA) and M. saltuarius(MS) were reported as the vectors of pinewood nematode, Bursaphelenchus xylophilus, in Korea. Aerial spray of pesticide in optimal occurrence period is the major way of prevention at pine wilt disease damaged area. To understand their regional distribution is the first step of prevention of the spread of pine wilt disease. However, it is not easy to identify them obviously because they are closely related not only biologically but also morphologically, in all developmental stages except adult. We designed PCR generic primer sets to amplify a segment of cytochrome oxidase subunit I (CO I) and internal transcribed spacer (ITS) and performed PCR with DNA extracted from larvae, pupae and adult of MA and MS. We cloned 850bp of CO I fragment and 1.3kbp of ITS fragment from 2 species. There were no distinctive differences between 2 species in sequence analysis of CO I. On the other hand, we developed species specific PCR primer sets to amplify ITS fragment of each Monochamus beetles and got the same result in larval, pupal and adult stage of each. These result shows that ITS is more proper method to identify 2 Monochamus beetles regardless of their developmental stages. In further study, we are planning to apply to other wood boring beetles in pine wilt disease damaged trees.

The molecular and behavioral effects of xenobiotic stress on immune and nervous systems of two honey bee species, *Apis mellifera* and *Apis cerana*

Ji Hyun Park[1], Doori Park[2], Hyung Wook Kwon[3]

[1]*Seoul National University, Republic of Korea,* [2]*Seoul National University, Republic of Korea,* [3]*Seoul National University, Republic of Korea*

Xenobiotic stresses induced by pesticides have been thought to disrupt the metabolic regulations in many organisms. The honey bee is an important social insect used for pollination in many crops, which has shown several symptoms of colony disruption caused by many environmental stress factors. In this study, we compared molecular and behavioral responses of two honey bee species, European honey bee, Apis mellifera and Asian honey bee, Apis cerana. These two honey bee species are likely to be exposed to pesticides-treated plants such as carbaryl in the field. Thus, here we investigated the effects of carbaryl on the regulation of gene induction in the immune and nervous systems as well as behavioral responses in A. mellifera and A. cerana. In combined with next generation sequencing analysis and learning behavioral paradigms in honey bees, we measured the expression levels of target genes involved in physiological stress and immunity. We also tested the proboscis extension response (PER) to determine the alternation of cognitive abilities in honey bees induced by carbaryl. This study will bring us better understandings of the impacts of xenobiotic stress factors on the immune and nervous system in two species, A. mellifera and A. cerana.

Modulation of olfactory sensitivity and behavioral response to diet-induced stress in *Drosophila melanogaster*

Jin Hee Kim[1], Je Won Jung[2], Hyung Wook Kwon[3]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Seoul National University, Republic of Korea

Obesity induced by consuming high-fat-diet (HFD) in humans and rodents is a main contributor to metabolic diseases such diabetes, hyperglycemia, hypertension, dyslipidemia, and cardiovascular diseases associated with insulin resistance. However, investigating effects and relationship between high-fat diet (HFD)-induced obesity and its olfactory sensitivity mediators have yet to be elucidated. To gain insights into how HFD-induced obesity affects olfactory sensitivity and neural behavioral responses, we here study Drosophila to test this hypothesis involving nutrient-sensing signal transduction pathways. Drosophila larvae reared on a high-fat diet showed hyperglycemic and insulin resistant. Also, they showed the increase of fat accumulations in the fat body compared with those reared on normal diets. Moreover, those larvae showed different patterns of food selection and locomotion behaviors, demonstrating the different level of gene expressions relevant to the homeostasis of lipid regulations. Remarkably, this modulation in feeding behaviors was accompanied with significant changes in olfactory sensitivity. Thus, this olfactory modulation induced by food stress in Drosophila might reflect functional variation and modification on feeding behaviors through nutrient-dependent metabolic sensing pathways.

Inhibitiory effect of water extracts from *Acanthocoris sordidus* on oxidative damage by ROS via its antioxidant activities

Young Mi Park[1], Jae Hwan Lim[2], Jong Eun Lee[3], Eul Won Seo[4]

[1]Andong National University, Republic of Korea, [2]Andong National University, Republic of Korea, [3]Andong National University, Republic of Korea, [4]Andong National University, Republic of Korea

Present study aimed to evaluate the effect of water extracts from Acanthocoris sordidus on antioxidant and biological activities. Even water extracts from A. sordidus showed low antioxidant activities, but removed DPPH free radical and hydroxyl radical by 48.9%, 37.8%, respectively and 80.0% of ferrous iron chelating activities. In addition, we tested the reducing activities of water extracts against oxidative cell and DNA damage. The water extracts from A. sordidus showed a protective effect on the oxidative cell damage by inhibiting the lipid peroxidation by 92.4%. Also we determined an increased level of p21 protein expression by 68.1%. The inhibition of DNA fragmentation were 53.3% and phosphorylation level of H2AX was 30.1% compared to the radical experimental group. Taken together, we suggest that the water extracts from A. sordidus has a role as chemopreventor substances against oxidative damage.

Effect of *Hydropsyche kozhantschikovi* extracts on oxidative cell and DNA damage

Young Mi Park[1], Jae Hwan Lim[2], Jong Eun Lee[3], Eul Won Seo[4]

[1]Andong National University, Republic of Korea, [2]Andong National University, Republic of Korea, [3]Andong National University, Republic of Korea, [4]Andong National University, Republic of Korea

In this study, we evaluated the protective effect of ethanol extracts from Hydropsyche kozhantschikovi on oxidative cell and DNA damage induced by free radical. Antioxidant activities of ethanol extracts from H. kozhantschikovi were low from scavenging activities of DPPH free radical and hydroxyl radical by 26.1% and 30.7% respectively and chelating ferrous iron by 26.2%. However, ethanol extracts from H. kozhantschikovi showed protective effects on the oxidative cell damage by inhibiting the lipid peroxidation by 99.2%, and showing an increased level of p21 protein expression by 92.2%. In addition, we tested the activities of extracts for reducing free radical-induced DNA damage. DNA fragmentation inhibition level in H. kozhantschikovi extracts was 70.3%, and inhibitory effect of phosphorylation of H2AX was 83.3% compared to the radical experimental group. In conclusion, although ethanol extract from H. kozhantschikovi showed a little antioxidant activities, it showed a strong protective effect on oxidative cell and DNA damage.

A microRNA-based screen for novel feeding-related target genes

Minjung Shin
KAIST, Republic of Korea

All organisms must match food intake with their metabolic needs. To do so, different species have developed feeding behaviors that vary widely in meal size, frequency, foraging strategy, and food preference. Well-regulated feeding is critical to growth, reproduction, and survival. To achieve appropriate balance, the brain must process internal information about nutrient stores and external information about available food sources and the immediate environment. We are interested in identifying novel genes and circuits involved in insect feeding behaviors. To do so, we have created a library of ~150 fly stocks that permit the tissue-specific overexpression of Drosophila microRNAs. MicroRNAs are single-stranded RNAs of approximately 22 nucleotides in length that play an important role in regulating gene expression by binding sequence-specifically to their target mRNAs and inducing their degradation. By crossing these UAS-miRNA lines to both fat body and pan-neuronal GAL4 drivers, we have identified miRNAs that enhance appetite in a modified Capillary Feeder (CAFE) assay. Oddly enough, the resulting prolonged overeating increases fly weight while reducing the size of fat body lipid droplets. Since all methods for bioinformatic prediction of miRNA targets are prone to generating false positives, we are carrying out a smaller secondary screen using UAS-RNAi lines for predicted targets to identify the specific target mRNA(s) being affected in the positive hits from the primary screen.

Female sex pheromone components of the box tree pyralid, *Glyphodes perspectalis* in Korea: Field test and development of film type formulation

Il-Kwon Park[1], Junheon Kim[2], Sang-Chul Shin[3]

[1]Korea Forest Research Institute, Republic of Korea, [2]Korea Forest Research Institute, Republic of Korea, [3]Korea Forest Research Institute, Republic of Korea

Box tree pyralid, Glyphodes perspectalis, is the most serious pest of box tree in Korea, and was recently introduced into Europe. The pheromone components of this moth have been identified as (Z)-11-hexadecenal (Z11-16:Ald), (E)-11-hexadecenal (E11-16:Ald), and (Z)-11-hexadecenol (Z-11-16:OH). The ratios of these three compounds were 5:0.96:0.2, respectively. In field bioassay, (Z)-11-hexadecenal or (E)-11-hexadecenal alone was not attractive to males, but the mixture of Z11-16:Ald and E11-16:Ald was attractive to males. The most effective ratios of Z11-16:Ald and E11-16:Ald was 5:1 and 7:1. (Z)-11-hexadecenol was the strong antagonist in field bioassay. Small amount of (Z)-11-hexadecenol inhibited attractiveness of male moth. To make a film type formulation of Glyphodes perspectalis pheromone, mixture of photo-setting resin, the mixture of Z11-16Ald and E11-16:Ald (5:1) and BHT was added and then homogenized. The mixture of resin and pheromones was applied to a polypropylene film (23 × 24 cm OHP film, Uchida, Tokyo, Japan) and spread over the film by a bar coater. In field bioassay, film type pheromone was more attractive than septum type pheromone.

A miRNA-based screen for novel genes involved in olfactory axon targeting

Shreelatha Shenoy
KAIST, Republic of Korea

One of the most interesting aspects of the Drosophila olfactory system is the incredible stereotypy with which it develops. The axons of sensory neurons expressing the same odorant receptors always manage to converge onto the same antennal lobe glomerulus. In order to identify novel genes that direct this precise and stereotyped connectivity of olfactory axons to their target glomeruli, we have generated a library of fly stocks that permit the tissue-specific overexpression of Drosophila miRNAs. Using the PNS driver pebbled-GAL4, we have overexpressed ~150 miRNAs in developing olfactory neurons as they enter the antennal lobe. We have identified 18 different miRNAs that disrupt olfactory axon guidance to the proper glomerulus. Since the available methods for miRNA target prediction are prone to generating false positives, we are currently carrying out a smaller secondary screen using UAS-RNAi lines for predicted targets to identify the specific target mRNA(s) that are being affected in the positive hits from our primary screen. It is our hope that this two-tiered screening method will expedite the identification of novel genes involved in olfactory axon guidance.

Why a membrane-anchored chitinase (CHT7) in *Tribolium?*

Mi Young Noh[1], Subbaratnam Muthukrishnan[2], Karl J. Kramer[3], Richard W. Beeman[4], Yasuyuki Arakane[5]

[1]Chonnam National University, Republic of Korea, [2]Kansas State University, U.S.A., [3]USDA-ARS Center for Grain and Animal Health Research, U.S.A., [4]USDA-ARS Center for Grain and Animal Health Research, U.S.A., [5]Chonnam National University, Republic of Korea

Insect chitinases (CHTs), which belong to family 18 glycosylhydrolases, have been detected in molting fluid and gut tissues and are predicted to mediate the digestion of chitin present in the exoskeleton and peritrophic matrix in the gut. Based on amino acid sequence similarity and phylogenetic analysis, insect CHT family proteins have been classified into eight groups. CHT7s belong to Group III chitinase contain two catalytic domains and one chitin binding domain (CBD). This group of chitinases, unlike most insect CHTs, possesses a predicted transmembrane segment at the N-terminal region. The recombinant T. castaneum CHT7 that was expressed in Hi-5 insect cells was bound to the cell membrane. Apparently, the catalytic domains of this CHT face the extracellular space as revealed by its ability to hydrolyze an artificial chitin substrate added to the medium. DsRNA-based functional studies (RNAi) for several CHT genes in Tribolium castaneum indicated that CHTs belong to groups I (TcCHT5) and II (TcCHT10) are critical for molting and turnover of chitin in the old cuticle. In other hand, RNAi for TcCHT7 did not affect any types of molting such as larval-larval, larval-pupal and pupal-adult. The resulting pupae (and adults), however, failed to wing-expansion and abdominal contraction. Interestingly, dsTcCHT7 injection significantly reduced the cuticular chitin in the elytra and body wall. Transmission electron microscopy revealed that down-regulation of TcCHT7 resulted in disorganize the cuticular chitin laminar. These results suggest that TcCHT7 may have critical roles in the laminar assembly and synthesis and/or deposition of cuticular chitin.

Temperature-dependent development of *Lymantria dispar* (Linne) (Lepidoptera: Lymantriidae)

Kwang-Su Lee[1], Heung-Sik Lee[2], Dong-Pyo Lyu[3], Chan-ki Hong[4]

[1]Animal Plant and Fisheries Quarantine and inspection Agency, Republic of Korea, [2]Animal Plant and Fisheries Quarantine and inspection Agency, Republic of Korea, [3]College of Life Science & Natural Resources, Sangji University, Republic of Korea, [4]College of Life Science & Natural Resources, Sangji University, Republic of Korea

Lymantria dispar (Linne) (Lepidoptera: Lymantriidae) is known for minor pest and is thinly populated in korea, whereas It's major invasive species causing a lot of damage in the eastern part of the Canada and U.S.. We experimented that the established life history and temperature effect on the emergence of L. dispar adults using egg mass collected at last winter and stored in cold room. Rearing conditions were as fllows: 70% R.H., photoperiodic control 14L:10D and temperature set to 15, 20, 25 and 30°C. All the processes of life history of the species were as below. The female emerged at each temperature: 15°C; 116.02, 20°C; 75.24, 25°C; 56.18 and 30°C; 45.70 days. The male emerged at each temperature: 15°C; 117.90, 20°C; 70.03, 25°C; 50.08 and 30°C; 41.09 days. The adult emergence was early in higher temperature. The female emerged earlier than the male. The mortality was increase in higher temperature. Therefore, the results of this study should aid in quarantine inside Canada and U.S..

Feeding behaviors of *Cacopsylla pyricola* (Homoptera: Psyllidae) and their changing feeding behaviors to insecticides

Min Woo Park[1], Shin Hyuk Jo[2], Sae Hee Kim[3], Hye Ri Kwon[4], Mi Ja Seo[5], Yong Man Yu[6], Young Nam Youn[7]

[1]Chungnam National University, Republic of Korea, [2]Chungnam National University, Republic of Korea, [3]Chungnam National University, [4]Chungnam National University, Republic of Korea, [5]Chungnam National University, Republic of Korea, [6]Chungnam National University, Republic of Korea, [7]Chungnam National University, Republic of Korea

The feeding behaviors of Cacopsylla pyricola and their changing feeding behaviors were recorded and analyzed with an electrical penetration graph (EPG) analysis against 5 insecticides. Feeding behaviors of C. pyricola monitored using the EPG technique; waveform PA which appears when it starts penetrates into the epidemic cell of pear leaf was occurred. And then waveform PB which its stylet secreted saliva was observed. Waveforms PC1 and PC2 involved the penetrating and sucking behavior in parenchyma cells. Otherwise, phloem salivation and ingestion behaviors produced waveforms PE1 and PE2. Ingestion in xylem tissue showed waveform PG. Among the feeding patterns of C. pyricola described above, phloem feeding pattern most frequently occurred, and xylem feeding pattern and parenchyma penetration pattern were appeared in the order. General feeding behavior patterns of C. pyricola were changed by insecticide treatments. The type and frequency of waveforms differently occurred depending on a sort of insecticides treated. In case of treatment of benfuracarb, total duration of non-probes (waveform Np) was appeared higher than any other insecticide. However, when flonicamid and deltamethrin were treatment, total duration of stylet penetration (waveform PA) and xylem ingestion (waveform PG) were appeared higher than other insecticide.

The insect intestinal bacteria were isolated from the gut of the predacious multicolored Asian ladybird beetle, Harmonia axyridis, and then their ability of degradation to casein, chitin, cellulose and lignin was examined. Thirty-five isolates including genus Arthrobacter were isolated and identified from the gut of H. axyridis. Staphylococcus saprophyticus and S. sciuri were isolated and identified from all larval and adult stages. For the conformed the intestinal bacteria in Turnip aphid, Lipaphis erysimi that was provided to H. axyridis as prey, aphids grinded and checked. There are 5 strains including S. sciuri that was isolated same as H. axyridis. As a result of cultured intestinal bacteria on the media contained with skim-milk, chitin, cellulose and lignin, 12 strains were showed casein and 4 strains were chitin degradation. Otherwise, there was not found strains with cellulose and lignin degradation ability.

Endogenous Cellulases, laminarinase, and mannanase found in some plant, fungi, bacteria, and animals are β-1,4-Endoglucanases, β-1,3-Endoglucanases and β-1,4-D-mannanase that belong to the glycosyl hydrolase family (GHF). They have gained industrial interest due to their ability to modify and degrade cellulose-containing polysaccharides in bioethanol production and the food and feed industries. Recently, the freezing-intolerant Antarctic springtail is known to have various carbohydrases to digest the ingested food in the cold environment. Previously, we succeeded production of endogenous GHs of antartic springtail in E.coli, but it has not been accomplished mass production. Here, we report the successful mass production, purification, and characterization of C. antaricticus cellulase (CaCEL), laminarinase (CaLAM), and mannanase (CaMAN) using B. mori as host. The CaCEL produced in the silkworm were N-glycosylated and the innermost GlcNAc residue is linked to a α-1,3 Fucose residue. In specific lectin affinity assays, the affinity of N-linked glycan was different from those produced in cytosolic and heamolymph cells. The yield of the purified rGHs of springtail was evidently high, and the activated enzyme proved enough to give a positive signal during the in vitro activity assay. The results suggested a potential application for heterologous expression of cellulases in insect for biomass conversion. *This work was supported by Bio-industry Technology Development Program of Korea Institute of Planning and Evaluation for Technology in Food, Agriculture, Forestry, and Fisheries.

Molecular characterization and apoptotic mechanisms of psacotheasin, a novel knottin-type antimicrobial peptide, from *Psacothea hilaris*

Jae-Sam Hwang[1], Bomi Hwang[2], Juneyoung Lee[3], Dong Gun Lee[4], Eun-Young Yun[5], In-Woo Kim[6], Sung-Hee Nam[7], Seong-Ryul Kim[8], Mi-Young Ahn[9]

[1]National Academy of Agricultural Science, RDA, Republic of Korea, [2]Kyungpook National University, Republic of Korea, [3]Kyungpook National University, Republic of Korea, [4]Kyungpook National University, Republic of Korea, [5]National Academy of Agricultural Science, RDA, Republic of Korea, [6]National Academy of Agricultural Science, RDA, Republic of Korea, [7]National Academy of Agricultural Science, RDA, Republic of Korea, [8]National Academy of Agricultural Science, RDA, Republic of Korea, [9]National Academy of Agricultural Science, RDA, Republic of Korea

We report the isolation and characterization of a novel knottin-type antimicrobial peptide from the yellow-spotted long-horned beetle Psacothea hilaris. A cDNA encoding a 56-mer knottin-type propeptide was identified and its predicted molecular mass and pI were 5.92 kDa and 8.28, respectively. A 34-mer mature peptide was also selected and named herein as psacotheasin. The antimicrobial activity of chemically synthesized psacotheasin against human bacterial pathogens was subsequently investigated. The results showed that psacotheasin exerted potent activities against both Gram-positive and Gram-negative bacterial strains. And we have further found that a series of characteristic cellular changes of apoptosis in C. albicans can be induced by the accumulation of intracellular reactive oxygen species, specifically hydroxyl radicals, the well-known important regulators of apoptosis.

Activities of glutathione S-transferase (GST) and GST mu isozyme, catalase (CAT), superoxide dismutase (SOD) as well as hemolymph proteins of host larvae (Ephestia kuehniella, Lepidoptera: Pyralidae)) of Bracon hebetor (Hymenoptera: Braconidae) were determined. Tissues of 6 host larvae were pooled for each analysis and 3 replicates were performed for enzyme assays each treatment and measured by using spectrophotometer. Time courses after paralization influence on the antioxidant defense enzymes in host larvae as well as total hemolymph protein is evident. Specific activities of CAT, GST and GST mu isozyme activity reached its highest level in the eighth hour. These values were gradually decreased up to 8 and 24 h after paralysis to control sample level, respectively. Total hemolymph proteins levels showed fluctuation during course of time after paralization and reach highest value in 24 hours. Our work represents the first study of GST and CAT activities in the host larvae of B. hebetor that it is very useful for host-parasitoid relationships.

Developing a molecular diagnosis key for five common cockroach species

Mohammad Ali Oshaghi[1], Hashemi-Aghdam S.S.[2], Fatemeh Mohtarami[3]

[1]Tehran University of Medical Sciences, Iran, [2]Tehran University of Medical Sciences, Iran, [3]Tehran University of Medical Sciences, Iran

Cockroaches are of vital importance medically and hygienically as they can transmit human pathogenic agents. In this study, the genetic structure of five Iranian cockroaches including Periplaneta americana, Pycnoscelus surinamensis, Blattella germanica, Blatta lateralis and Blatta orientals has been examined using sequence analysis of mtDNA-COI gene to develop a molecular identification key for them. DNA was extracted and the barcode region of COI gene was amplified and sequenced using conserved primers. The sequences were analyzed to construct phylogenetic trees and to provide a physical map to introduce appropriate enzyme/s (RFLP markers) for molecular diagnosis of the five species. Inter-population variation (3%) was observed in P.americana but other species. Surinam cockroaches were the most diverged species (10%) among species. Cockroaches of Turkestani and Oriental at the DNA level and Turkestani and American at the amino acid level were the most similar species respectively. AluI enzyme by providing species-specific RFLP profiles could differentiate the species. This molecular marker, which is proposed to identify the five specimens, is new to science. Phylogenetic analysis revealed topography matched well with morphological classification. There was a very close relationship between oriental and turkestani cockroaches. P.americana populations maintain a high genetic diversity compared with other species. Seemingly, repeated exposure to mutational agents such as chemical poisons, local gene flow, and emigration from different parts of the world may the causes of such high genetic variations. Molecular key represented in this study can be applied for the molecular systematic of Cockroaches in scientific centers worldwide.

TYLCV acquisition influenced the attraction of whiteflies Bemisia tabaci to the green light emitting diodes (LEDs)

S. M. Hemayet Jahan[1], Kwan-Suk Lee[2], Sukchan Lee[3], Kyeong-Yeoll Lee[4]

[1]Kyungpook National University, Republic of Korea, [2]National Institutes of Agricultural Science, Republic of Korea, [3]Sungkyunkwan University, Suwon, Republic of Korea, [4]Kyungpook National University, Republic of Korea

Light attraction of whiteflies and thrips was compared using LED light bulbs that exhibit different wavelengths of visible and UV ranges. Whiteflies, both Bemisia tabaci and Trialeurodes vaporariorum, are mostly attracted to green LED (526 nm) while thrips, Frankliniella occidentalis, attracted to UV LED (371 nm). The attraction of green LED was higher in B. tabaci than T. vaporariorum while its rate was not different between B biotype and Q biotype of B. tabaci. We demonstrated whether TYLCV acquisition influences on the light attraction of B. tabaci. TYLCV infected B. tabaci was 4 times higher in the attraction to the green light LED than TYLCV free ones. Those attraction rates were significantly different in a 0.5 m distance to the light source but were similar at more than 1 m distance. Our results show that B. tabaci favors green light and its attraction is highly enhanced by the acquisition of a plant virus, TYLCV.

Up-regulation of temperature susceptibility in *Bemisia tabaci* upon acquisition of *Tomato Yellow Leaf Curl Virus* (TYLCV)

Joseph Carlo A. Pusag[1], S. M. Hemayet Jahan[2], Kwan-Suk Lee[3], Sukchan Lee[4], Kyeong-Yeoll Lee[5]

[1]Kyungpook National University, Republic of Korea, [2]Kyungpook National University, Republic of Korea, [3]National Institutes of Agricultural Science, Republic of Korea, [4]Sungkyunkwan University, Suwon, Republic of Korea, [5]Kyungpook National University, Republic of Korea

Acquisition of plant viruses has various effects on physiological mechanisms in vector insects. Bemisia tabaci is the only known vector of Tomato yellow leaf curl virus (TYLCV), which is a serious virus affecting tomato cultivars. In this study, the lifespan of Q1 biotype was compared between non-viruliferous (NV) and TYLCV-viruliferous (V) whiteflies. Total lifespan from egg to adult death was 10.64 days shorter in V than NV whiteflies. We investigated the temperature susceptibility of B. tabaci by comparing mortalities as well as heat shock protein (hsp) mRNA levels between NV and V whiteflies. For this, NV and V whiteflies were exposed for either 1 or 3 h at 4, 25, and 35°C. The mortality of V whiteflies was higher than NV ones following exposure at either 4°C or 35°C, but there was no significant difference at 25°C. Analysis of the expression level of heat shock protein (hsp) genes using quantitative real-time PCR showed that both cold and heat shock treatments stimulated higher expression of hsps (hsp40, hsp70, and hsp90) at various rates in V whiteflies than NV ones, but there was no difference at 25°C. All together, our results show that TYLCV acquisition accelerated the developmental rate and increased susceptibility to thermal stress in B. tabaci. Therefore, this modification may result in reduced vector longevity due to increased metabolic energy utilization. Our results provide insights into the complex interaction between vector fitness and thermal stress during the acquisition and transmission of plant viruses.

The induction and termination of larval diapause in *Lycaena dispar*

Seong-hyun Kim[1], Namjung Kim[2], Seong-Jin Hong[3], Young-Bo Lee[4], Hae-Chul Park[5], Yeon-Ho Je[6]

[1]National Academy of Agricultural Science, Republic of Korea, [2]National Academy of Agricultural Science, Republic of Korea, [3]National Academy of Agricultural Science, Republic of Korea, [4]National Academy of Agricultural Science, Republic of Korea, [5]National Academ of Agricultural Science, Republic of Korea, [6]Seoul National University, Republic of Korea

This study investigated the effects of photoperiod and temperature on larval diapause in the Large Copper butterfly, Lycaena dispar. This information was collected for use in establishing an indoor-rearing system for the Large Copper. Lycaena dispar requires 3~4 generations to complete its life cycle due to larval diapause. The induction of larval diapause was studied in this species for different combinations of temperature (15, 20, 25°C) and photoperiod (LD 14:10, 12:12, 10:14, 8:16). Most larvae entered diapause under short-day conditions but developed without diapause under long-day conditions (LD 14:10). However, 72% of the larvae entered diapause under long-day conditions (LD 14:10) at 15°C. The average developmental periods (>25 days) of larvae at 15°C were longer than those (<13 days) at 25°C. The duration of diapause induced by LD 10:14 at 15°C was significantly longer than the duration of diapause induced by other conditions. An examination of the sensitivity of immature larvae to low temperatures revealed that 1st instars showed susceptibility if diapause was induced by short-day conditions (LD 8:16, 20°C). To compare the effects of temperature and total periods of chilling on the termination of diapause, larvae were subjected to different chilling temperatures (3, 5, and 8°C) from 60 days of age. The rate of termination of diapause at 3 and 8°C was significantly higher than that at 20°C. However, pupation differed significantly among insects treated at 8°C.

Cloning and sequence analysis of a GH10 Endo-β-1,4-xylanase gene of *Streptomyces mexicanus* DY31, a bacterium in the gut of a mole cricket, *Gryllotalpa orientalis*

Do Young Kim[1], Hyo Jeong Kim[2], Han-Young Cho[3], Yi-Joon Kim[4], Dong-Ha Shin[5], Kwang-Hee Son[6], Ho-Yong Park[7]

[1]Industrial Bio-materials Research Center, KRIBB, Republic of Korea, [2]Industrial Bio-materials Research Center, KRIBB, Republic of Korea, [3]Industrial Bio-materials Research Center, KRIBB, [4]Insect Biotech Co. Ltd., Daejeon, Republic of Korea, [5]Insect Biotech Co. Ltd., Daejeon 305-811, Republic of Korea, [6]Industrial Bio-materials Research Center, KRIBB, Republic of Korea, [7]Industrial Bio-materials Research Center, KRIBB, Republic of Korea

A hemicellulolytic bacterium capable of degrading β-1,4-xylans and β-1,4-mannans, Streptomyces mexicanus DY31, was isolated from the gut of a mole cricket, Gryllotalpa orientalis. In this study, we cloned and molecularly analyzed a novel, extracellular endo-β-1,4-xylanase (XylZ) gene of the bacterium by repeated genomic walking and nested PCR protocols. The cloned gene (1350-bp) was predicted to encode a polypeptide consisting of 449 amino acids with a deduced molecular mass of 46,798.8 Da and a calculated isoelectric point of 6.24. When analyzed by the SignalP 3.0 server, the enzyme was also predicted to have a unique N-terminal signal sequence (from Met1 to Ala30) of 30 amino acids. The results of a protein blast survey showed that XylZ was a modular endo-β-1,4-xylanase comprised of a catalytic GH10 domain (from Tyr44 to Leu332) in the N-terminus region and a carbohydate-binding module II (from Cys351 to Gly444) in the C-terminus region, respectively. This domain architecture of XylZ was most similar to that of Streptomyces lividans TK24 endo-β-1,4-xylanase (GenBank accession no.: EFD71285). However, the maximum sequence identity (85%) was oberved when the catalytic GH10 domain of XylZ was compared to that of Streptomyces sp. SirexAA-E endo-β-1,4-xylanase (GenBank accession no.: AEN08210), which has not yet been biochemically characterized.

Indoor-rearing system of the emma field cricket, *Teleogryllus emma*

NamJung Kim[1], Seong-Hyun Kim[2], Seong-Jing Hong[3], Young-Bo Lee[4], Seok-Jo Whang[5], Hae-Chul Park[6]

[1]National Academy of Agricultural Science, Republic of Korea, [2]National Academy of Agricultural Science, Republic of Korea, [3]National Academy of Agricultural Science, Republic of Korea, [4]National Academy of Agricultural Science, Republic of Korea, [5]National Academy of Agricultural Science, Republic of Korea, [6]National Academy of Agricultural Science, Republic of Korea

To study the ecological characteristics of the emma cricket, Teleogryllus emma, development, reproduction, oviposition, and diapause of T. emma were investigated. The developmental periods of T. emma nymphs had a range of 124.8 days to 44.4 days at 21℃ and 35℃, respectively. At 15℃ and 18℃, however, all tested individuals died before emergence. The highest average fecundity per female was 737.3 at 25℃. In order to study the added effect of photoperiod, the nymphs of T. emma were reared under various photoperiods. The mean nymphal stages were 65 days in a 0-hour photoperiod, 49-50 days in an 8-, 10-, 12-, or 13-hour photoperiod, 59 days in a 14-hour photoperiod and 64 days in a 16-hour photoperiod. The nymphs matured faster in the short compared to the long photoperiods. Egg-forming and preservation methods were essential for a year-round rearing system of T. emma eggs, as T. emma undergo one generation per year. An oviposition preference experiment using different mats, soil (natural oviposition mat) and oasis® (artificial oviposition mat) showed that T. emma preferred to oviposit on the oasis® mat. Changes in volume, oxygen consumption, and water content in T. emma eggs were followed from oviposition. An increase in volume, oxygen consumption and uptake of water occurred from 7 to 8 days following oviposition. Oxygen consumption of eggs increased slowly for 7 days following oviposition, but decreased until 15 days following oviposition. These results showed that a physiological change at diapause initiation was reflected upon volume, water content, and oxygen consumption of

A fibrolytic Paenibacillus sp. strain HJ-8 was isolated from the gut of a wood-attacking longicorn beetle, Moechotypa diphysis. This microorganism was able to efficiently decompose hemicellulosic materials such as β-1,4-xylans and β-1,4-mannans, whereas it could not degrade cellulose. In this study, we purified and characterized an extracellular β-1,4-mannanase (ManA) produced by the bacterium that was grown on a galactomannan (locust bean gum). ManA was purified by two consecutive column chromatography using Phenyl-Sepharose and Superdex 200 resins, respectively. The N-terminal amino acid sequence and molecular mass of ManA was analyzed to be APSFAVGADFSYVPG and 31.0 kDa. The enzyme displayed its maximum catalytic activity toward locust bean gum at 55oC and pH 7.0. In addition, the half-life of ManA at 55oC was evaluated to be approximately 25 min. The enzyme was capable of readily decomposing different mannan compounds such as locust bean gum, guar gum, ivory nut mannan, and mannooligosaccharides, while it had no effect on cellulose, soluble starch, β-1,4-xylans, p-nitrophenol (PNP)-glucopyranoside, PNP-xylopyranoside, or PNP-cellobioside. The results of HPLC analysis revealed that ManA could degrade locust bean gum to a series of oligosaccharides [M1 (0.5%), M2 (1.5%), M3 (2.5%), M4 (9.6%), M5 (54.1%), and M6 (31.8%)]. ManA was tightly bound to insoluble ivory nut mannan and Avicel, whereas it did not exhibit any binding capacity towards other hydrophobic materials such as insoluble oat spelt xylan, lignin, chitin, chitosan, and curdlan.

Development of a mycoinsecticide formulation with *Paecilomyces lilacinus* HY-4 for the control of Tetranychus urticae

Zhen Ji[1], Han-Young Cho[2], Do Young Kim[3], Yi-Joon Kim[4], Dong-Ha Shin[5], Kwang-Hee Son[6], Ho-Yong Park[7]

[1]Industrial Bio-materials Research Center, KRIBB, Republic of Korea, [2]Industrial Bio-materials Research Center, KRIBB, Republic of Korea, [3]Industrial Bio-materials Research Center, KRIBB, [4]Insect Biotech Co., Ltd., Daejeon, Republic of Korea, [5]Insect Biotech Co., Ltd., Daejeon, Republic of Korea, [6]Industrial Biomaterials Research Center, KRIBB, Republic of Korea, [7]Industrial Bio-materials Research Center, KRIBB, Republic of Korea

Three types of propagules including aerial conidia, blastospores, and mycelia were employed to evaluate the shelf-life and thermostability of a biological control strain Paecilomyces lilacinus HY-4, which was used for manufacture of the mycoinsecticide to reduce the amount of conventional chemical pesticides in crop production systems. Compared to the high germination rate (>95%) of aerial conidia after 120d at ambient temperature (20±3oC), blastospores gave a survival rate of 12.7% only, and no germination was found in mycelia after 90d of storage. Therefore, the aerial conidia harvested through solid state fermentation by using inexpensive substrate rice bran were served for the wettable powder formulation of fungal pesticide- PaeciPora®. Bioassay trials were conducted on greenhouse-grown cucumbers, our results demonstrated the formulation exhibited a control efficacy of 63.7% against the adult females of Tetranychus urticae at 1×107 conidia/mL after 7d. This study indicates the novel mycopesticide PaeciPora® may be considered as promising for a new approach to control T. urticae in organic integrated pest management.

Increase of 30K protein in identified motoneurons by hemolymph results in inhibition of programmed cell death in silkworm, *Bombyx mori* (Lepidoptera, Bombycidae)

Hwa Young Song[1], Mi Young Kim[2], Bong Hee Lee[3]

[1]Korea University, Republic of Korea, [2]Korea University, Republic of Korea, [3]Korea University, Republic of Korea

This study demonstrates that a 30K protein was gradually synthesized in primary-cultured motoneurons from the accessory planta retractor (APR) of the 6th abdominal ganglion (APR6) in silkworm ventral ganglia through stimulation of hemolymph. An increase in 30K protein synthesis resulted in an inhibition of programmed cell death (PCD) of APR6 motoneurons. The 30K protein was gradually synthesized from the 30Kc6 gene of identified APR6s in day-6 4th instars to day-9 5th instar larvae, but synthesis of the 30K protein ceased in isolated APR6s of day-1 pupa, which normally begin to undergo PCD. When pupal APR6s were treated with larval hemolymph, however, the 30K protein was synthesized suggesting the existence of an anti-PCD factor in the larval hemolymph. An increase of 30K protein within the APR6s was confirmed by antiserum made against the recombinant 30K protein that originated from the APR 30Kc6 gene. Larval APR6, in which PCD was induced with 20-hydroxyecdysone (20E) added to the primary culture, exhibited some PCD characteristics of shrinkage of cell bodies, axonal fragmentation and loss of mitochondrial function. These results provide new insights on the survival or PCD of insect motoneurons through stimulation of hemolymph

To investigate genes related to innate immune system in T. molitor larva that was treated with acholeplasma lysate, we constructed cDNA library and analyzed expressed sequence taq (EST) sequences. All the sequences determined by single-pass sequencing were trimmed from the vector region and the low-quality sequences. We collected 1966 unique sequences composed of 1340 singletons and 254 contigs with an average 727 bp in untreated group and 1962 unique sequences composed of 1348 singletons and 240 contigs with an average 661 bp in treated group. These T. molitor EST sequences were searched against NCBI nr database by local BLAST (blastx, E<e-5). The 1726 putative sequences and 1732 putative sequences had significant hits within the database. To predict the potential functions of the genes, KOG (clusters of orthologous groups for eukaryotic complete genomes) analysis was conducted (blastx, E<e-10). As a result, 1154 genes and 1218 genes were significantly matched. Of these, most of genes were belongs to O category (Posttranslational modification, protein turnover, chaperones). Here, we identified up-regulated and/or down-regulated genes by acholeplasma lysate injection. Our results would be helpful to further study of innate immune mechanism in conjunction with mycoplasma.

The Korean isolate of Pieris rapae granulovirus (PrGV) genome was sequenced and analyzed. The double-stranded circular genome contains 108,658 bp and potentially encodes 120 predicted open reading frames (ORFs). BLAST searches followed by a comparison of ORF arrangement with those of completely sequenced granulovirus genomes showed the presence of 78 homologs to other genes in the database. In addition, three uncharacterized ORFs were observed and relate to ORF 9, 32 and 117 in both the Korean and Chinese isolates of PrGV in comparison with other sequenced GV genomes. The analysis predicted 120 ORFs with a size of above 50 amino acid residues showing minimal overlap. The 120 putative ORFs covered 92% of the sequenced genome. The genome had an A+T content of 66%, similar to the sequenced Chinese isolate and was close to CrleGV and ChocGV, with the highest A+T content of 67.6% and 67.3% respectively. The genomes of both the Korean and Chinese isolate of PrGV exhibit extensive sequence similarity and co-linearity and the identity figures reflect almost 99% homology. The mean overall amino acid identity of PrGV ORFs with other GV genomes was highest with ChocGV ORFs at 58%. The 120 predicted ORFs were grouped according to function into 10 genes involved in transcription, 11 genes involved in replication, 21 structural protein genes, 14 auxiliary genes and 61 unknown genes. Chitinase (ORF 10) and cathepsin (ORF11) genes were found in the genome, explaining the typical degradation patterns of the infected Pieris rapae larvae. The granulin gene (ORF 1)

CSP and takeout genes modulate the aggregation behavior in locust

Wei Guo
Institute of Zoology, Chinese Academy of Sciences, China

The migratory locust, Locusta migratoria, is a worldwide agricultural pest whose outbreaks can result in plagues during which they mass migrate in marching bands and flying swarms. A key step in the formation of large aggregation is the initial shift from the strong mutual aversion in solitarious locusts to the attraction to each other in gregarious locusts. This behavioral plasticity defines the most striking trait in locust phase change. However, the genetic basis for behavioral plasticity in locusts is largely unknown. To unravel the molecular mechanisms underlying the behavioral phase change, we developed a large-scale oligonucleotide microarray to quantify the expression of 9154 genes during the time courses of isolating gregarious locusts and crowding solitarious locusts. We found that several olfaction-related genes, CSPs and takeout, are strongly regulated in a total of 1,444 differentially expressed genes during both processes and display opposite expression trends in response to population density change. Tissue expression experiments revealed that CSPs and takeout genes exhibited antenna-rich expressions. RNA interference combined with olfactory behavioral experiments confirmed that the CSPs and takeout genes are involved in the rapid switch from repulsion to attraction between individuals during gregarization and the reverse transition during solitarization. These findings suggest that the response to locust-emitted olfactory cues regulated by CSP and takeout genes is involved in the behavioral phase change in the migratory locust and provide a previously undescribed molecular mechanism linked to the formation of locust aggregations.

Roles of a chitinase gene (*LmCht10*) in *Locusta migratoria* development

Daqi Li[1], Kun Yan Zhu[2], Sheng Li[3], Enbo Ma[4], Yi Sun[5], Jianzhen Zhang[6]

[1]Shanxi University, China, [2]Kansas State University, U.S.A., [3]Shanghai institutes for biological sciences, CAS, China, [4]Shanxi University, China, [5]Shanxi University, China, [6]Shanxi University, China

Insect chitinases (EC 3.2.1.14, endochitinases) are enzymes catalyzing random hydrolysis of β-1-4 glycosidic bonds in chitin and chitodextrins. Multiple chitinase genes have been identified in various insect species, but their roles in insect development have not been well elucidated. We identified a chitinase gene (LmCht10) from Locusta migratoria, which was highly expressed in the integument. By using RNA interference in different nymph stages, we observed that nymphs injected with dsRNA for LmCht10 developed slowly, failed to detach from the old cuticle during molting process and showed high mortality (>95%). When the expression of LmCht10 was suppressed by RNAi, we observed significantly retarded new cuticle development and cuticle thickness as compared to the dsRNA GFP-injected controls. We further found that the developmental expression patterns of LmCht10 were correlated well with the change in 20-hydroxyecdysone (20E) titers from day 1 of the fourth-instar nymph stage to the 7-day-old adult stage. LmCht10 was quickly up-regulated after 20E was injected into the 2-day-old fifth-instar nymphs. Injection of cycloheximide (CHI) along with 20HE did not abolish the up-regulation of expression of LmCht10 indicating that new protein synthesis was not required for the elevated expression of this gene by 20HE. In contrast, LmCht10 was dramatically down-regulated in day 5, 6 and 7 of fifth-instar nymphs after RNAi of ecdysone receptor in day-2 fifth-instar nymphs. These results suggest that LmCht10 is a target gene for 20-HE and that its expression is directly induced by this hormone during nymph development.

Endocrine regulation of the peripheral clock gene expression in an insect model

Adam Bajgar[1], David Dolezel[2], Marcela Buricova[3], Magdalena Hodkova[4]

[1]University of South Bohemia, Czech Republic, [2]Academy of Sciences, Czech Republic, [3]University of South Bohemia, Czech Republic, [4]Academy of Sciences, Czech Republic

The linden bug Pyrrhocoris apterus exhibits a robust diapause response to photoperiod. Daily changes in the circadian clock gene expression were very week, but photoperiod strongly affected the basal levels of gene transcripts via the neuroendocrine system. In the gut, cryptochrome (cry) mRNA levels were much higher (about 10x) in diapause-promoting short days (SD) than in reproduction-promoting long days (LD), while Par Domain Protein 1 (Pdp1) mRNA levels were higher in LD than in SD. The effect of photoperiod on gene expression was mediated by the insulin producing neurosecretory cells of the pars intercerebralis (PI) and the juvenile hormone (JH) producing corpus allatum (CA). In LD-females, CA-ablation resulted in SD-like levels of gene transcripts, while PI-ablation had very little effect. In SD-females, the situation was opposite; PI-ablation resulted in LD-like levels of gene transcripts, while CA-ablation had no effect. Thus the CA is responsible for LD-like characteristics of gene expression in reproducing females and the PI (probably via inhibitory effect on the CA) is responsible for SD-like characteristics of gene expression in diapausing females. Levels of period (per) mRNA were not significantly affected by hormonal conditions. In contrast to the gut, cry mRNA levels in the fat body were not influenced by photoperiod, but levels of per and Pdp1 transcripts were inversely affected by contrasting photoperiods and the CA. Our results indicate that the peripheral clock gene expression reflects rather the physiological state of females (with respect to diapause or reproduction) than the external light-dark cycle. Common and distinct juvenile hormone signaling pathways regulate metamorphosis and reproduction in hemimetabolous insects

Adam Bajgar[1], Vlastimil Smykal[2], Jan Provaznik[3], Marcela Buricova[4], David Dolezel[5], Marek Jindra[6], Magdalena Hodkova[7]

[1]University of South Bohemia, Czech Republic, [2]University of South Bohemia, Czech Republic, [3]University of South Bohemia, [4]Faculty of Sciences, Czech Republic, [5]Academy of Sciences, Czech Republic, [6]Academy of Sciences, Czech Republic, [7]Academy of Sciences, Czech Republic

Juvenile hormone (JH), produced by the corpus allatum gland (CA), prevents metamorphosis in insect larvae and stimulates vitellogenesis in adult females. Whether both processes rely on the same JH signaling pathway is presently unknown. We examine the function of three JH-signaling genes: Methoprene-tolerant (Met), Taiman, and Kruppel-homolog 1 (Kr-h1) using systemic RNAi in larvae and adults of the hemimetabolous firebug, Pyrrhocoris apterus. In this species, Met conveys the JH signal to prevent premature metamorphosis by maintaining high expression of Kr-h1 (1). In contrast to Met and Kr-h1, injection of Taiman dsRNA did not produce premature adult development. In adult females of P. apterus, knockout of either Met or Taiman suppressed both vitellogenin synthesis and ovarian development. A similar effect was produced by ablation of the CA or by a natural absence of JH during reproductive diapause. Stimulation of vitellogenesis by treatment of diapause females with a JH mimic methoprene required both Met and Taiman. In contrast to Met and Taiman, injection of Kr-h1 dsRNA did not prevent stimulation of vitellogenesis by JH. Our results indicate that JH signaling pathways in larvae and adults of P. apterus include both common and distinct components. While the JH receptor Met operates in both larvae and adults, its partner Taimain is only required for vitellogenesis but not for the maintenance of the larval program. Conversely, Kr-h1 blocks adult development but is dispensable for vitellogenesis. 1 Konopova B., Smykal V., Jindra M. (2011) Plos ONE 6 (12): e28728 Acknowledgements: Grant GACR P502/10/1612

A new coelomic gregarine parasite from the ghost moth, *Thitarodes pui* (Lepidoptera: Hepialidae)

Zixuan Sun[1], Wenjing Wu[2], Guren Zhang[3]

[1]Sun Yat-sen University, China, [2]Sun Yat-sen University, China, [3]Sun Yat-sen University, China

Gregarines, a variety of apicomplexan parasites, inhabit the intestine, coelom or reproductive vesicle of invertebrates including insects. Recently, we discovered a coelomic gregarine parasite from Thitarodes pui distributed at 4,156~4,600m in the Tibet Plateau. The ghost moth is known as a host species of entomopathogenic fungus Ophiocordyceps sinensis with medical and economical importance. Visible gregarine gametocysts were found in the coelom of T. pui adult hosts, containing tens of thousands of biconical oocysts. In this work, lots of trophozoites were found in the intestinal lumen of T.pui larvae fed with 10^3 oocysts/larva. Young trophozoites were characterized by a protomerite-deutomerite septum and a flowerlike epimerite. The septum was lost in mature trophozoites (obovoid, 40~100 μm). Morphological characters of oocysts and trophozoites suggest that the gregarine species is closely related to the genus Paraschneideria, which is consistent with previous phylogenetic analysis inferred from SSU rDNA sequences.
